Getting Started

1.1 What is Yii

Yii is a high-performance component-based PHP framework for developing large-scale Web applications. It enables maximum reusability in Web programming and can significantly accelerate the development process. The name Yii (pronounced as /i:/) stands for easy, efficient and extensible.

1.1.1 Requirements

To run an Yii-powered Web application, you need a Web server supporting PHP 5.1.0 or higher.

For developers who want to use Yii, understanding object-oriented programming (OOP) is very helpful, because Yii is a pure OOP framework.

1.1.2 What is Yii Best for?

Yii is a generic Web programming framework that can be used for developing virtually all sorts of Web applications. Because it is light-weighted and equipped with sophisticated caching solutions, it is especially suitable for developing high-traffic applications, such as portals, forums, content management systems (CMS), e-commerce systems, etc.

1.1.3 How is Yii Compared with Other Frameworks?

Like most PHP frameworks, Yii is an MVC framework.

Yii excels over other PHP frameworks in that it is efficient, feature-rich and clearly-documented. Yii is carefully designed from the beginning to fit for serious Web application development. It is neither a byproduct of some project nor a conglomerate of third-party work. It is the result of the authors' rich experience of Web application development and the investigation and reflection of the most popular Web programming frameworks and

applications.

1.2 Installation

Installation of Yii mainly involves the following two steps:

- 1. Download Yii Framework from yiiframework.com.
- 2. Unpack the Yii release file to a Web-accessible directory.

Tip: Yii does not need to be installed under a Web-accessible directory. An Yii application has one entry script which is usually the only file that needs to be exposed to Web users. Other PHP scripts, including those from Yii, should be protected from Web access since they may be exploited for hacking.

1.2.1 Requirements

After installing Yii, you may want to verify that your server satisfies all the requirements of using Yii. You can do so by accessing the requirement checker script at the following URL in a Web browser:

http://hostname/path/to/yii/requirements/index.php

The minimum requirement by Yii is that your Web server supports PHP 5.1.0 or above. Yii has been tested with Apache HTTP server on Windows and Linux operating systems. It may also run on other Web servers and platforms provided PHP 5 is supported.

1.3 Creating First Yii Application

To get an initial experience with Yii, we describe in this section how to create our first Yii application. We will use the powerful yiic tool which can be used to automate code creation for several purposes. We assume that YiiRoot is the directory where Yii is installed.

Run yiic on the command line as follows:

% YiiRoot/framework/yiic webapp WebRoot/testdrive

Note: When running yiic on Mac OS, Linux or Unix, you may need to change the permission of the yiic file so that it is executable. You may also use php YiiRoot/framework/yiic.php to replace yiic.

This will create a skeleton Yii application under the directory WebRoot/testdrive, where WebRoot stands for the document root of your Web server. The application is a good starting point for adding more features as it has all the needed directories and files.

Without writing a single line of code, we can test drive our first Yii application by accessing the following URL in a Web browser:

```
http://hostname/testdrive/index.php
```

As we can see, the application has three pages: the homepage, the contact page and the login page. The homepage shows some information about the application as well as the user login status, the contact page displays a contact form that users can fill in to submit their inquiries, and the login page allows users to be authenticated before accessing privileged contents. See the following screenshots for more details.

The following diagram shows the directory structure of our application. Please see Conventions for detailed explanation about this structure.

```
testdrive/
  index.php
                             Web application entry script file

      controllers/
                             containing controller class files
         SiteController.php the default controller class
```

1. Getting Started

My Web Application

Home Contact Login

Welcome, Guest!

This is the homepage of My Web Application. You may modify the following files to customize the content of this

D:\wwwroot\testdrive\protected\controllers\SiteController.php

This file contains the SiteController class which is the default application controller. Its default index action renders the content of the following two files. D:\wwwroot\testdrive\protected\views\site\index.php

This is the view file that contains the body content of this page.

D:\wwwroot\testdrive\protected\views\layouts\main.php
This is the layout file that contains common presentation (such as header, footer) shared by all view files.

What's Next

- Implement new actions in SiteController, and create corresponding views under D:\www.root\testdrive \protected\views\site
- Create new controllers and actions manually or using the yiic tool.
- If your Web application should be driven by database, do the following:
 Set up database connection by configuring the db component in the application configuration. D:\www.root\testdrive\protected\config\main.php
 - Create model classes under the directory D:\www.root\testdrive\protected\models
 Implement CRUD operations for a model class. For example, for the Post model class, you would create
 - a PostController class together with create, read, update and delete actions Note, the yiic tool can automate the task of creating model classes and CRUD operations.

If you have problems in accomplishing any of the above tasks, please read Yii documentation or visit Yii forum for

      index.php
      login.php
                       the view for 'login' action
                       containing system view files
   system/
```

1.3.1 Connecting to Database

Most Web applications are backed by databases. Our test-drive application is not an exception. To use a database, we first need to tell the application how to connect to it. This is done by changing the application configuration file WebRoot/testdrive/protected/config/main.php, as shown below:

```
return array(
.....
'components'=>array(
.....
'db'=>array(
'connectionString'=>'sqlite:protected/data/source.db',
),
```

8 1. Getting Started

```
),
.....
```

In the above, we add a db entry to components, which instructs the application to connect to the SQLite database WebRoot/testdrive/protected/data/source.db when needed.

Note: To use Yii's database feature, we need to enable PHP PDO extension and the driver-specific PDO extension. For the test-drive application, we would need the php_pdo and php_pdo_sqlite extensions to be turned on.

To this end, we need to prepare a SQLite database so that the above configuration can be effective. Using some SQLite admin tool, we can create a database with the following schema:

```
CREATE TABLE User (
   id INTEGER NOT NULL PRIMARY KEY AUTOINCREMENT,
   username VARCHAR(128) NOT NULL,
   password VARCHAR(128) NOT NULL,
   email VARCHAR(128) NOT NULL
);
```

For simplicity, we only create a single User table in our database. The SQLite database file is saved as WebRoot/testdrive/protected/data/source.db. Note that both the file and the containing directory must be made writable by the Web server process, as required by SQLite.

1.3.2 Implementing CRUD Operations

Now is the fun part. We would like to implement the CRUD (create, read, update and delete) operations for the User table we just created. This is also commonly needed in practical applications.

Again, we use the yiic tool to help us generate the needed code. This process is also known as *scaffolding*.

```
% cd WebRoot/testdrive
% YiiRoot/framework/yiic shell
Yii Interactive Tool v1.0
Please type 'help' for help. Type 'exit' to quit.
```

```
>> model User
   generate User.php
The 'User' class has been successfully created in the following file:
    D:\wwwroot\testdrive\protected\models\User.php
If you have a 'db' database connection, you can test it now with:
    $model=User::model()->find();
    print_r($model);
>> crud User
   generate UserController.php
   generate create.php
      mkdir D:/wwwroot/testdrive/protected/views/user
   generate update.php
   generate list.php
   generate show.php
Crud 'user' has been successfully created. You may access it via:
http://hostname/path/to/index.php?r=user
```

In the above, we use the shell command of yiic to interact with our newly created application. At the prompt, we can enter a valid PHP statement or expression to evaluate and print it. We can also perform tasks such as model and crud as shown above. The model command automatically generates a User model class based on the schema of the User table. And the crud command generates the controller class and views that implement the CRUD operations for the User model.

Note: If you make any change to your code or configuration, please re-enter yiic shell so that the new code or configuration can take effect. Also make sure you are using the right PHP CLI to execute yiic. Otherwise you may encounter errors like "...could not find driver", even though you are sure you have already enabled PDO and the corresponding database driver. The reason for such kind of errors is often because the wrong PHP CLI is using an unexpected php.ini.

Let's enjoy our work by browsing the following URL:

```
http://hostname/testdrive/index.php?r=user
```

This will display a list of user entries in the User table. Since our table is empty, nothing will appear at the moment.

Click the New User link on the page. We will be brought to the login page if we have not logged in before. After logged in, we are shown with an input form that allows us to add

1. Getting Started

a new user entry. Complete the form and click on the Create button. If there is any input error, a nice error prompt will be shown which prevents us from saving the input. Back to the user list, we should see the newly added user appearing in the list.

Repeat the above steps to add more users. Notice that user list page will automatically paginate the user entries if there are too many to be displayed in one page.

If we login as an administrator using admin/admin, we can view the user admin page with the following URL:

http://hostname/testdrive/index.php?r=user/admin

This will show us a nice table of user entries. We can click on the table header cells to sort the corresponding columns. And like the user list page, the admin page also performs pagination when there are too many user entries to be displayed in one page.

All these nice features come without requiring us to write a single line of code!

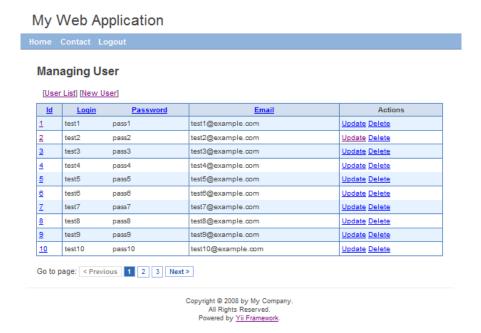

Figure 1.6: User admin page

My Web Application New User [User List] [Manage User] Please fix the following input errors: Login cannot be blank. Password cannot be blank. Email cannot be blank. Copyright © 2008 by My Company. All Rights Reserved. Powered by Yii Framework.

Figure 1.7: Create new user page

Fundamentals

2.1 Model-View-Controller (MVC)

Yii implements the model-view-controller (MVC) design pattern which is widely adopted in Web programming. MVC aims to separate business logic from user interface considerations so that developers can more easily change each part without affecting the other. In MVC, the model represents the information (the data) and the business rules; the view contains elements of the user interface such as text, form inputs; and the controller manages the communication between the model and the view.

Besides MVC, Yii also introduces a front-controller, called application, which represents the execution context of request processing. Application resolves the user request and dispatches it to an appropriate controller for further handling.

The following diagram shows the static structure of an Yii application:

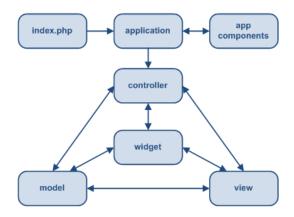

Figure 2.1: Static structure of Yii application

2. Fundamentals

2.1.1 A Typical Workflow

The following diagram shows a typical workflow of an Yii application when it is handling a user request:

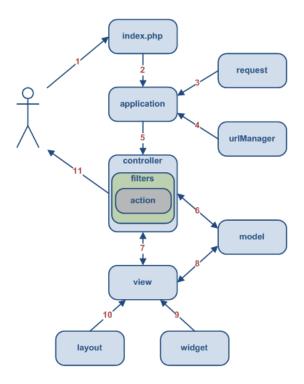

Figure 2.2: A typical workflow of Yii application

- 1. A user makes a request with the URL http://www.example.com/index.php?r=post/show&id=1 and the Web server handles the request by executing the bootstrap script index.php.
- 2. The bootstrap script creates an application instance and runs it.
- 3. The application obtains the detailed user request information from an application component named request.
- 4. The application determines the requested controller and action with the help of an application component named urlManager. For this example, the controller is post which refers to the PostController class; and the action is show whose actual meaning is determined by the controller.
- 5. The application creates an instance of the requested controller to further handle the user request. The controller determines that the action show refers to a method

named actionShow in the controller class. It then creates and executes filters (e.g. access control, benchmarking) associated with this action. The action is executed if it is allowed by the filters.

- 6. The action reads a Post model whose ID is 1 from the database.
- 7. The action renders a view named show with the Post model.
- 8. The view reads and displays the attributes of the Post model.
- 9. The view executes some widgets.
- 10. The view rendering result is embedded in a layout.
- 11. The action completes the view rendering and displays the result to the user.

2.2 Entry Script

Entry script is the bootstrap PHP script that handles user requests initially. It is the only PHP script that end users can directly request to execute.

In most cases, entry script of an Yii application contains the code that is as simple as follows,

```
// remove the following line when in production mode
defined('YII_DEBUG') or define('YII_DEBUG', true);
// include Yii bootstrap file
require_once('path/to/yii/framework/yii.php');
// create application instance and run
$configFile='path/to/config/file.php';
Yii::createWebApplication($configFile)->run();
```

The script first includes the Yii framework bootstrap file yii.php. It then creates a Web application instance with the specified configuration and runs it.

2.2.1 Debug Mode

An Yii application can run in either debug or production mode according to the constant value YII_DEBUG. By default, this constant value is defined as false, meaning production mode. To run in debug mode, define this constant as true before including the yii.php file. Running application in debug mode is less efficient because it keeps many internal logs. On the other hand, debug mode is also more helpful during development stage because it provides richer debugging information when error occurs.

16 2. Fundamentals

2.3 Application

Application represents the execution context of request processing. Its main task is to resolve the user request and dispatch it to an appropriate controller for further processing. It also serves as the central place for keeping application-level configurations. For this reason, application is also called front-controller.

Application is created as a singleton by the entry script. The application singleton can be accessed at any place via Yii::app().

2.3.1 Application Configuration

By default, application is an instance of CWebApplication. To customize it, we normally provide a configuration file (or array) to initialize its property values when the application instance is being created. An alternative way of customizing application is to extend CWebApplication.

The configuration is an array of key-value pairs. Each key represents the name of a property of the application instance, and each value the corresponding property's initial value. For example, the following configuration configures the name and defaultController properties of the application.

```
array(
    'name'=>'Yii Framework',
    'defaultController'=>'site',
)
```

We usually store the configuration in a separate PHP script (e.g. protected/config/main. php). Inside the script, we return the configuration array as follows,

```
return array(...);
```

To apply the configuration, we pass the configuration file name as a parameter to the application's constructor, or to Yii::createWebApplication() like the following, which is usually done in the entry script:

```
$app=Yii::createWebApplication($configFile);
```

2.3 Application 17

Tip: If the application configuration is very complex, we can split it into several files, each returning a portion of the configuration array. Then, in the main configuration file, we call PHP <code>include()</code> to include the rest configuration files and merge them into a complete configuration array.

2.3.2 Application Base Directory

Application base directory refers to the root directory that contains all security-sensitive PHP scripts and data. By default, it is a subdirectory named protected that is located under the directory containing the entry script. It can be customized via setting the basePath property in the .

Contents under the application base directory should be protected from being accessed by Web users. With Apache HTTP server, this can be done easily by placing a .htaccess file under the base directory. The content of the .htaccess file is as follows,

deny from all

2.3.3 Application Component

Functionalities of application can be easily customized and enriched with its flexible component architecture. Application manages a set of application components, each implementing specific features. For example, application resolves a user request with the help of CUrlManager and CHttpRequest components.

By configuring the components property of application, we can customize the class and property values of any application component used in an application. For example, we can configure CMemCache component so that it can use multiple memcache servers for caching,

18 2. Fundamentals

In the above, we add the cache element to the components array. The cache element states that the class of the component is CMemCache and its servers property should be initialized as such.

To access an application component, use Yii::app()->ComponentID, where ComponentID refers to the ID of the component (e.g. Yii::app()->cache).

An application component may be disabled by setting enabled to be false in its configuration. Null is returned when we access a disabled component.

Tip: By default, application components are created on demand. This means an application component may not be created at all if it is not accessed during a user request. As a result, the overall performance may not be degraded even if an application is configured with many components. Some application components (e.g. CLogRouter) may need to be created no matter they are accessed or not. To do so, list their IDs in the preload property of the application.

2.3.4 Core Application Components

Yii predefines a set of core application components to provide features common among Web applications. For example, the request component is used to resolve user requests and provide information such as URL, cookies. By configuring the properties of these core components, we can change the default behaviors of Yii in nearly every aspect.

Below we list the core components that are pre-declared by CWebApplication.

- assetManager: CAssetManager manages the publishing of private asset files.
- authManager: CAuthManager manages role-based access control (RBAC).
- cache: CCache provides data caching functionality. Note, you must specify the actual class (e.g. CMemCache, CDbCache). Otherwise, null will be returned when you access this component.
- clientScript: CClientScript manages client scripts (javascripts and CSS).
- coreMessages: CPhpMessageSource provides translated core messages used by Yii framework.
- db: CDbConnection provides the database connection. Note, you must configure its connectionString property in order to use this component.
- errorHandler: CErrorHandler handles uncaught PHP errors and exceptions.

2.3 Application 19

• messages: CPhpMessageSource - provides translated messaged used by Yii application.

- request: CHttpRequest provides information related with user requests.
- securityManager: CSecurityManager provides security-related services, such as hashing, encryption.
- session: CHttpSession provides session-related functionalities.
- statePersister: CStatePersister provides global state persistence method.
- urlManager: CUrlManager provides URL parsing and creation functionality.
- user: CWebUser represents the identity information of the current user.
- themeManager: CThemeManager manages themes.

2.3.5 Application Lifecycles

When handling a user request, an application will undergo the following lifecycles:

- 1. Set up class autoloader and error handling;
- 2. Register core application components;
- 3. Load application configuration;
- 4. Initialize application with CApplication::init()
 - Load static application components;
- 5. Raise onBeginRequest event;
- 6. Process the user request:
 - Resolve the user request;
 - Create controller;
 - Run controller; 7.Raise on EndRequest event;

2. Fundamentals

2.4 Controller

A controller is an instance of CController or its child class. It is created by application when the user requests for it. When a controller runs, it performs the requested action which usually brings in the needed models and renders an appropriate view. An action, at its simplest form, is just a controller class method whose name starts with action.

A controller has a default action. When the user request does not specify which action to execute, the default action will be executed. By default, the default action is named as index. It can be changed by setting CController::defaultAction.

Below is the minimal code needed by a controller class. Since this controller does not define any action, requesting for it would throw an exception.

```
class SiteController extends CController
{
}
```

2.4.1 Route

Controllers and actions are identified by IDs. Controller ID is in the format of path. to.xyz which corresponds to the controller class file protected/controllers/path/to/XyzController.php, where the token xyz should be replaced by actual names (e.g. post corresponds to protected/controllers/PostController.php). Action ID is the action method name without the action prefix. For example, if a controller class contains a method named actionEdit, the ID of the corresponding action would be edit.

Users request for a particular controller and action in terms of route. A route is formed by concatenating a controller ID and an action ID separated by a slash. For example, the route post/edit refers to PostController and its edit action. And by default, the URL http://hostname/index.php?r=post/edit would request for this controller and action.

Note: By default, routes are case-sensitive. Since version 1.0.1, it is possible to make routes case-insensitive by setting CUrlManager::caseSensitive to be false in the application configuration. When in case-insensitive mode, make sure you follow the convention that directories containing controller class files are in lower case, and both controller map action map are using keys in lower case.

2.4.2 Controller Instantiation

A controller instance is created when CWebApplication handles an incoming request. Given the ID of the controller, the application will use the following rules to determine

2.4 Controller 21

what the controller class is and where the class file is located.

• If CWebApplication::catchAllRequest is specified, a controller will be created based on this property, and the user-specified controller ID will be ignored. This is mainly used to put the application under maintenance mode and display a static notice page.

- If the ID is found in CWebApplication::controllerMap, the corresponding controller configuration will be used to create the controller instance.
- If the ID is in the format of 'path.to.xyz', the controller class name is assumed to be Xyz and the corresponding class file is protected/controllers/path/to/XyzController.php. For example, a controller ID admin.user would be resolved as the controller class UserController and the class file protected/controllers/admin/UserController.php. If the class file does not exist, a 404 CHttpException will be raised.

2.4.3 Action

As aforementioned, an action can be defined as a method whose name starts with the word action. A more advanced way is to define an action class and ask the controller to instantiate it when requested. This allows actions to be reused and thus introduces more reusability.

To define a new action class, do the following:

```
class UpdateAction extends CAction
{
    public function run()
    {
        // place the action logic here
    }
}
```

In order for the controller to be aware of this action, we override the actions() method of our controller class:

22 2. Fundamentals

```
);
}
}
```

In the above, we use the path alias application.controllers.post.UpdateAction to specify that the action class file is protected/controllers/post/UpdateAction.php.

Writing class-based actions, we can organize an application in a modular fashion. For example, the following directory structure may be used to organize the code for controllers:

```
protected/
controllers/
PostController.php
UserController.php
post/
CreateAction.php
ReadAction.php
UpdateAction.php
user/
CreateAction.php
ListAction.php
ProfileAction.php
UpdateAction.php
```

2.4.4 Filter

Filter is a piece of code that is configured to be executed before and/or after a controller action executes. For example, an access control filter may be executed to ensure that the user is authenticated before executing the requested action; a performance filter may be used to measure the time spent in the action execution.

An action can have multiple filters. The filters are executed in the order that they appear in the filter list. A filter can prevent the execution of the action and the rest unexecuted filters.

A filter can be defined as a controller class method. The method name must begin with filter. For example, the existence of the filterAccessControl method defines a filter named accessControl. The filter method must be of the signature:

```
public function filterAccessControl($filterChain)
{
    // call $filterChain->run() to continue filtering and action execution
}
```

2.4 Controller 23

where \$filterChain is an instance of CFilterChain which represents the filter list associated with the requested action. Inside the filter method, we can call \$filterChain->run() to continue filtering and action execution.

A filter can also be an instance of CFilter or its child class. The following code defines a new filter class:

```
class PerformanceFilter extends CFilter
{
    protected function preFilter($filterChain)
    {
        // logic being applied before the action is executed
        return true; // false if the action should not be executed
    }

    protected function postFilter($filterChain)
    {
        // logic being applied after the action is executed
    }
}
```

To apply filters to actions, we need to override the CController::filters() method. The method should return an array of filter configurations. For example,

The above code specifies two filters: postOnly and PerformanceFilter. The postOnly filter is method-based (the corresponding filter method is defined in CController already); while the PerformanceFilter filter is object-based. The path alias application.filters. PerformanceFilter specifies that the filter class file is protected/filters/PerformanceFilter. We use an array to configure PerformanceFilter so that it may be used to initialize the

2. Fundamentals

property values of the filter object. Here the unit property of PerformanceFilter will be initialized as 'second'.

Using the plus and the minus operators, we can specify which actions the filter should and should not be applied to. In the above, the postOnly should be applied to the edit and create actions, while PerformanceFilter should be applied to all actions EXCEPT edit and create. If neither plus nor minus appears in the filter configuration, the filter will be applied to all actions.

2.5 Model

A model is an instance of CModel or its child class. Models are used to keep data and their relevant business rules.

A model represents a single data object. It could be a row in a database table or a form of user inputs. Each field of the data object is represented as an attribute of the model. The attribute has a label and can be validated against a set of rules.

Yii implements two kinds of models: form model and active record. They both extend from the same base class CModel.

A form model is an instance of CFormModel. Form model is used to keep data collected from user inputs. Such data are often collected, used and then discarded. For example, on a login page, we can use a form model to represent the username and password information that are provided by an end user. For more details, please refer to Working with Form

Active Record (AR) is a design pattern used to abstract database access in an object-oriented fashion. Each AR object is an instance of CActiveRecord or its child class, representing a single row in a database table. The fields in the row are represented as properties of the AR object. Details about AR can be found in Active Record.

2.6 View

A view is a PHP script consisting of mainly elements of user interface. It can contain PHP statements, but it is recommended that these statements should not alter data models and should remain relatively simple. For the spirit of separation of logic and presentation, large chunk of logic should be placed in controller or model instead of view.

A view has a name which is used to identify the view script file when rendering. The name of a view is the same as the name of its view script file. For example, view edit refers to a view script file named as edit.php. To render a view, call CController::render() with the name of the view. The method will look for the corresponding view file under

2.6 View 25

the directory protected/views/ControllerID.

Inside the view script, we can access the controller instance using \$this. We can thus pull in any property of the controller by evaluating \$this->propertyName in the view.

We can also use the following push approach to pass data to the view:

```
$this->render('edit', array(
    'var1'=>$value1,
    'var2'=>$value2,
));
```

In the above, the render() method will extract the second array parameter into variables. As a result, in the view script we can access local variables \$var1 and \$var2.

2.6.1 Layout

Layout is a special view that is used to decorate views. It usually contains portions of user interface that are common among several views. For example, a layout may contain header and footer portions and embed the content view in between,

```
.....header here......
<?php echo $content; ?>
.....footer here.....
```

where \$content stores the rendering result of the content view.

Layout is implicitly applied when calling render(). By default, the view script protected/views/layouts/main.php is used as the layout. This can be customized by changing either CWebApplication::layout or CController::layout. To render a view without applying any layout, call renderPartial() instead.

2.6.2 Widget

A widget is an instance of CWidget or its child class. It is a component mainly for presentational purpose. Widgets are usually embedded in a view script to generate some complex yet self-contained user interface. For example, a calendar widget can be used to render a complex calendar user interface. Widgets enable better reusability in user interface.

To use a widget, do as follows in a view script:

2. Fundamentals

```
<?php $this->beginWidget('path.to.WidgetClass'); ?>
...body content that may be captured by the widget...
<?php $this->endWidget(); ?>

Or

<?php $this->widget('path.to.WidgetClass'); ?>
```

The latter is used when the widget does not need any body content.

Widgets can be configured to customize its behaviors. This is done by settings their initial property values when calling CBaseController::beginWidget or CBaseController::widget. For example, when using CMaskedTextField widget, we would like to specify the mask being used. We can do so by passing an array of those property initial values as follows, where the array keys are property names and array values the initial values of the corresponding widget properties:

```
<?php
$this->widget('CMaskedTextField',array(
        'mask'=>'99/99/9999'
));
?>
```

To define a new widget, extend CWidget and override its init() and run() methods:

```
class MyWidget extends CWidget
{
    public function init()
    {
        // this method is called by CController::beginWidget()
    }
    public function run()
    {
        // this method is called by CController::endWidget()
    }
}
```

Like a controller, a widget can also have its own view. By default, widget view files are located under the views subdirectory of the directory containing the widget class file. These views can be rendered by calling CWidget::render(), similar to that in controller. The only difference is that no layout will be applied to a widget view.

2.7 Component 27

2.6.3 System View

System views refer to the views used by Yii to display error and logging information. For example, when a user requests for a non-existing controller or action, Yii will throw an exception explaining the error. Yii displays the exception using a specific system view.

The naming of system views follows some rules. Names like errorXXX refer to views for displaying CHttpException with error code XXX. For example, if CHttpException is raised with error code 404, the error404 view will be displayed.

Yii provides a set of default system views located under framework/views. They can be customized by creating the same-named view files under protected/views/system.

2.7 Component

Yii applications are built upon components which are objects written to a specification. A component is an instance of CComponent or its derived class. Using a component mainly involves accessing its properties and raising/handling its events. The base class CComponent specifies how to define properties and events.

2.7.1 Component Property

A component property is like an object's public member variable. We can read its value or assign a value to it. For example,

To define a component property, we can simply declare a public member variable in the component class. A more flexible way, however, is by defining getter and setter methods like the following:

```
public function getTextWidth()
{
    return $this->_textWidth;
}

public function setTextWidth($value)
{
    $this->_textWidth=$value;
}
```

2. Fundamentals

The above code defines a writable property named textWidth (the name is case-insensitive). When reading the property, getTextWidth() is invoked and its returned value becomes the property value; Similarly, when writing the property, setTextWidth() is invoked. If the setter method is not defined, the property would be read-only and writing it would throw an exception. Using getter and setter methods to define a property has the benefit that additional logic (e.g. performing validation, raising events) can be executed when reading and writing the property.

Note: There is a slight difference between a property defined via getter/setter methods and a class member variable. The name of the former is case-insensitive while the latter is case-sensitive.

2.7.2 Component Event

Component events are special properties that take methods (called event handlers) as their values. Attaching (assigning) a method to an event will cause the method to be invoked automatically at the places where the event is raised. Therefore, the behavior of a component can be modified in a way that may not be foreseen during the development of the component.

A component event is defined by defining a method whose name starts with on. Like property names defined via getter/setter methods, event names are case-insensitive. The following code defines an onClicked event:

```
public function onClicked($event)
{
    $this->raiseEvent('onClicked', $event);
}
```

where \$event is an instance of CEvent or its child class representing the event parameter.

We can attach a method to this event as follows:

```
$component->onClicked=$callback;
```

where \$callback refers to a valid PHP callback. It can be a global function or a class method. If the latter, the callback must be given as an array: array(\$object,'methodName').

The signature of an event handler must be as follows:

2.7 Component 29

```
function methodName($event)
{
    .....
}
```

where \$event is the parameter describing the event (it originates from the raiseEvent() call). The \$event parameter is an instance of CEvent or its derived class. At the minimum, it contains the information about who raises the event.

If we call onClicked() now, the onClicked event will be raised (inside onClicked()), and the attached event handler will be invoked automatically.

An event can be attached with multiple handlers. When the event is raised, the handlers will be invoked in the order that they are attached to the event. If a handler decides to prevent the rest handlers from being invoked, it can set \$event-i.handled to be true.

2.7.3 Component Behavior

Starting from version 1.0.2, a component has added support for mixin and can be attached with one or several behaviors. A *behavior* is an object whose methods can be 'inherited' by its attached component through the means of collecting functionality instead of specialization (i.e., normal class inheritance). A component can be attached with several behaviors and thus achieve 'multiple inheritance'.

Behavior classes must implement the IBehavior interface. Most behaviors can extend from the CBehavior base class. If a behavior needs to be attached to a model, it may also extend from CFormBehavior or CActiveRecordBehavior which implements additional features specifc for models.

To use a behavior, it must be attached to a component first by calling the behavior's attach() method. Then we can call a behavior method via the component:

```
// $name uniquely identifies the behavior in the component
$behavior->attach($name,$component);
// test() is a method of $behavior
$component->test();
```

An attached behavior can be accessed like a normal property of the component. For example, if a behavior named tree is attached to a component, we can obtain the reference to this behavior object using:

```
$behavior=$component->tree;
```

30 2. Fundamentals

```
// equivalent to the following:
// $behavior=$component->asa('tree');
```

A behavior can be temporarily disabled so that its methods are not available via the component. For example,

```
$component->disableBehavior($name);
// the following statement will throw an exception
$component->test();
$component->enableBehavior($name);
// it works now
$component->test();
```

It is possible that two behaviors attached to the same component have methods of the same name. In this case, the method of the first attached behavior will take precedence.

When used together with , behaviors are even more powerful. A behavior, when being attached to a component, can attach some of its methods to some events of the component. By doing so, the behavior gets a chance to observe or change the normal execution flow of the component.

2.8 Path Alias and Namespace

Yii uses path aliases extensively. A path alias is associated with a directory or file path. It is specified in dot syntax, similar to that of widely adopted namespace format:

```
RootAlias.path.to.target
```

where RootAlias is the alias of some existing directory. Yii predefines two aliases: system and application. The former is the alias of the Yii framework directory, while the latter is the alias of the application's protected directory. We can call YiiBase::setPathOfAlias() to define new path aliases (including root aliases).

By using YiiBase::getPathOfAlias(), an alias can be translated to its corresponding path. For example, system.web.CController would be translated as yii/framework/web/CController.

Using aliases, it is very convenient to import the definition of a class. For example, if we want to include the definition of the CController class, we can call the following:

```
Yii::import('system.web.CController');
```

2.9 Conventions 31

The import method differs from include and require in that it is more efficient. The class definition being imported is actually not included until it is referenced for the first time. Importing the same namespace multiple times is also much faster than include_once and require_once.

Tip: When referring to a class defined by the Yii framework, we do not need to import or include it. All core Yii classes are pre-imported.

We can also use the following syntax to import a whole directory so that the class files under the directory can be automatically included when needed.

```
Yii::import('system.web.*');
```

Besides import, aliases are also used in many other places to refer to classes. For example, an alias can be passed to Yii::createComponent() to create an instance of the corresponding class, even if the class file was not included previously.

Do not confuse path alias with namespace. A namespace refers to a logical grouping of some class names so that they can be differentiated from other class names even if their names are the same, while path alias is used to refer to a class file or directory. Path alias does not conflict with namespace.

Tip: Because PHP prior to 5.3.0 does not support namespace intrinsically, you cannot create instances of two classes who have the same name but with different definitions. For this reason, all Yii framework classes are prefixed with a letter 'C' (meaning 'class') so that they can be differentiated from user-defined classes. It is recommended that the prefix 'C' be reserved for Yii framework use only, and user-defined classes be prefixed with other letters.

2.9 Conventions

Yii favors conventions over configurations. Follow the conventions and one can create sophisticated Yii applications without writing and managing complex configurations. Of course, Yii can still be customized in nearly every aspect with configurations when needed.

Below we describe conventions that are recommended for Yii programming. For convenience, we assume that WebRoot is the directory that an Yii application is installed at.

32 2. Fundamentals

2.9.1 URL

By default, Yii recognizes URLs with the following format:

http://hostname/index.php?r=ControllerID/ActionID

The r GET variable refers to the route that can be resolved by Yii into controller and action. If ActionID is omitted, the controller will take the default action (defined via CController::defaultAction); and if ControllerID is also omitted (or the r variable is absent), the application will use the default controller (defined via CWebApplication::defaultController).

With the help of CUrlManager, it is possible to create and recognize more SEO-friendly URLs, such as http://hostname/ControllerID/ActionID.html. This feature is covered in detail in URL Management.

2.9.2 Code

Yii recommends naming variables, functions and class types in camel case which capitalizes each word in the name and joins them without spaces. Variable and function names should have their first word all in lower-case, in order to differentiate from class names (e.g. \$basePath, runController(), LinkPager). For private class member variables, it is recommended to prefix their names with an underscore character (e.g. \$_actionList).

Because namespace is not supported prior to PHP 5.3.0, it is recommended that classes be named in some unique way to avoid name conflict with third-party classes. For this reason, all Yii framework classes are prefixed with letter "C".

A special rule for controller class names is that they must be appended with the word Controller. The controller ID is then defined as the class name with first letter in lower case and the word Controller truncated. For example, the PageController class will have the ID page. This rule makes the application more secure. It also makes the URLs related with controllers a bit cleaner (e.g. /index.php?r=page/index instead of /index.php?r=PageController/index).

2.9.3 Configuration

A configuration is an array of key-value pairs. Each key represents the name of a property of the object to be configured, and each value the corresponding property's initial value. For example, array('name'=>'My application', 'basePath'=>'./protected') initializes the name and basePath properties to their corresponding array values.

Any writable properties of an object can be configured. If not configured, the properties

2.9 Conventions 33

will take their default values. When configuring a property, it is worthwhile to read the corresponding documentation so that the initial value can be given properly.

2.9.4 File

Conventions for naming and using files depend on their types.

Class files should be named after the public class they contain. For example, the CController class is in the CController.php file. A public class is a class that may be used by any other classes. Each class file should contain at most one public class. Private classes (classes that are only used by a single public class) may reside in the same file with the public class.

View files should be named after the view name. For example, the index view is in the index.php file. A view file is a PHP script file that contains HTML and PHP code mainly for presentational purpose.

Configuration files can be named arbitrarily. A configuration file is a PHP script whose sole purpose is to return an associative array representing the configuration.

2.9.5 Directory

Yii assumes a default set of directories used for various purposes. Each of them can be customized if needed.

- WebRoot/protected: this is the application base directory holding all security-sensitive PHP scripts and data files. Yii has a default alias named application associated with this path. This directory and everything under should be protected from being accessed by Web users. It can be customized via CWebApplication::basePath.
- WebRoot/protected/runtime: this directory holds private temporary files generated during runtime of the application. This directory must be writable by Web server process. It can be customized via CApplication::runtimePath.
- WebRoot/protected/extensions: this directory holds all third-party extensions. It can be customized via CApplication::extensionPath.
- WebRoot/protected/controllers: this directory holds all controller class files. It can be customized via CWebApplication::controllerPath.
- WebRoot/protected/views: this directory holds all view files, including controller views, layout views and system views. It can be customized via CWebApplication::viewPath.

34 2. Fundamentals

• WebRoot/protected/views/ControllerID: this directory holds view files for a single controller class. Here ControllerID stands for the ID of the controller. It can be customized via CController::getViewPath.

- WebRoot/protected/views/layouts: this directory holds all layout view files. It can be customized via CWebApplication::layoutPath.
- WebRoot/protected/views/system: this directory holds all system view files. System views are templates used in displaying exceptions and errors. It can be customized via CWebApplication::systemViewPath.
- WebRoot/assets: this directory holds published asset files. An asset file is a private file that may be published to become accessible to Web users. This directory must be writable by Web server process. It can be customized via CAssetManager::basePath.
- WebRoot/themes: this directory holds various themes that can be applied to the application. Each subdirectory represents a single theme whose name is the subdirectory name. It can be customized via CThemeManager::basePath.

2.10 Development Workflow

Having described the fundamental concepts of Yii, we show the common workflow for developing a web application using Yii. The workflow assumes that we have done the requirement analysis as well as the necessary design analysis for the application.

- 1. Create the skeleton directory structure. The yiic tool described in Creating First Yii Application can be used to speed up this step.
- 2. Configure the application. This is done by modifying the application configuration file. This step may also require writing some application components (e.g. the user component).
- 3. Create a model class for each type of data to be managed. Again, yiic can be used to automatically generate the active record class for each interested database table.
- 4. Create a controller class for each type of user requests. How to classify user requests depends on the actual requirement. In general, if a model class needs to be accessed by users, it should have a corresponding controller class. The yiic tool can automate this step, too.
- 5. Implement actions and their corresponding views. This is where the real work needs to be done.
- 6. Configure necessary action filters in controller classes.

- 7. Create themes if the theming feature is required.
- 8. Create translated messages if internationalization is required.
- 9. Spot data and views that can be cached and apply appropriate caching techniques.
- 10. Final tune up and deployment.

For each of the above steps, test cases may need to be created and performed.

36 2. Fundamentals

Working with Forms

3.1 Working with Form

Collecting user data via HTML forms is one of the major tasks in Web application development. Besides designing forms, developers need to populate the form with existing data or default values, validate user input, display appropriate error messages for invalid input, and save the input to persistent storage. Yii greatly simplifies this workflow with its MVC architecture.

The following steps are typically needed when dealing with forms in Yii:

- 1. Create a model class representing the data fields to be collected;
- 2. Create a controller action with code that responds to form submission.
- 3. Create a form in the view script file associated with the controller action.

In the next subsections, we describe each of these steps in detail.

3.2 Creating Model

Before writing the HTML code needed by a form, we should decide what kind of data we are expecting from end users and what rules these data should comply with. A model class can be used to record these information. A model, as defined in the Model subsection, is the central place for keeping user inputs and validating them.

Depending on how we make use of the user input, we can create two types of model. If the user input is collected, used and then discarded, we would create a form model; if the user input is collected and saved into database, we would use an active record instead. Both types of model share the same base class CModel which defines the common interface needed by form. **Note:** We are mainly using form models in the examples of this section. However, the same can also be applied to active record models.

3.2.1 Defining Model Class

Below we create a LoginForm model class used to collect user input on a login page. Because the login information is only used to authenticate the user and does not need to be saved, we create LoginForm as a form model.

```
class LoginForm extends CFormModel
{
   public $username;
   public $password;
   public $rememberMe=false;
}
```

Three attributes are declared in LoginForm: \$username, \$password and \$rememberMe. They are used to keep the user-entered username and password, and the option whether the user wants to remember his login. Because \$rememberMe has a default value false, the corresponding option when initially displayed in the login form will be unchecked.

Info: Instead of calling these member variables properties, we use the name *attributes* to differentiate them from normal properties. An attribute is a property that is mainly used to store data coming from user input or database.

3.2.2 Declaring Validation Rules

Once a user submits his inputs and the model gets populated, we need to make sure the inputs are valid before using them. This is done by performing validation of the inputs against a set of rules. We specify the validation rules in the rules() method which should return an array of rule configurations.

```
class LoginForm extends CFormModel
{
   public $username;
   public $password;
   public $rememberMe=false;

   public function rules()
```

The above code specifies that username and password are both required, password should be authenticated.

Each rule returned by rules() must be of the following format:

```
array('AttributeList', 'Validator', 'on'=>'ScenarioList', ...additional options)
```

where AttributeList is a string of comma-separated attribute names which need to be validated according to the rule; Validator specifies what kind of validation should be performed; the on parameter is optional which specifies a list of scenarios where the rule should be applied; and additional options are name-value pairs which are used to initialize the corresponding validator's property values.

There are three ways to specify Validator in a validation rule. First, Validator can be the name of a method in the model class, like authenticate in the above example. The validator method must be of the following signature:

```
/**
 * @param string the name of the attribute to be validated
 * @param array options specified in the validation rule
 */
public function ValidatorName($attribute,$params) { ... }
```

Second, Validator can be the name of a validator class. When the rule is applied, an instance of the validator class will be created to perform the actual validation. The additional options in the rule are used to initialize the instance's attribute values. A validator class must extend from CValidator.

Note: When specifying rules for an active record model, we can use a special option named on. The option can be either 'insert' or 'update' so that the rule is applied only when inserting or updating the record, respectively. If not set, the rule would be applied in both cases when save() is called.

Third, Validator can be a predefined alias to a validator class. In the above example, the name required is the alias to CRequiredValidator which ensures the attribute value being validated is not empty. Below is the complete list of predefined validator aliases:

- captcha: alias of CCaptchaValidator, ensuring the attribute is equal to the verification code displayed in a CAPTCHA.
- compare: alias of CCompareValidator, ensuring the attribute is equal to another attribute or constant.
- email: alias of CEmailValidator, ensuring the attribute is a valid email address.
- default: alias of CDefaultValueValidator, assigning a default value to the specified attributes.
- file: alias of CFileValidator, ensuring the attribute contains the name of an uploaded file.
- filter: alias of CFilterValidator, transforming the attribute with a filter.
- in: alias of CRangeValidator, ensuring the data is among a pre-specified list of values.
- length: alias of CStringValidator, ensuring the length of the data is within certain range.
- match: alias of CRegularExpressionValidator, ensuring the data matches a regular expression.
- numerical: alias of CNumberValidator, ensuring the data is a valid number.
- required: alias of CRequiredValidator, ensuring the attribute is not empty.
- type: alias of CTypeValidator, ensuring the attribute is of specific data type.

- unique: alias of CUniqueValidator, ensuring the data is unique in a database table column.
- url: alias of CUrlValidator, ensuring the data is a valid URL.

Below we list some examples of using the predefined validators:

```
// username is required
array('username', 'required'),
// username must be between 3 and 12 characters
array('username', 'length', 'min'=>3, 'max'=>12),
// when in register scenario, password must match password2
array('password', 'compare', 'compareAttribute'=>'password2', 'on'=>'register'),
// when in login scenario, password must be authenticated
array('password', 'authenticate', 'on'=>'login'),
```

3.2.3 Securing Attribute Assignments

Note: scenario-based attribute assignment has been available since version 1.0.2.

After a model instance is created, we often need to populate its attributes with the data submitted by end-users. This can be done conveniently using the following massive assignment:

```
$model=new LoginForm;
if(isset($_POST['LoginForm']))
    $model->setAttributes($_POST['LoginForm'], 'login');
```

The last statement is a massive assignment which assigns every entry in \$_POST['LoginForm'] to the corresponding model attribute in the login scenario (specified as the second parameter). It is equivalent to the following assignments:

```
foreach($_POST['LoginForm'] as $name=>$value)
{
    if($name is a safe attribute)
        $model->$name=$value;
}
```

The task of deciding whether a data entry is safe or not is based the return value of a method named safeAttributes and the specified scenario. By default, the method returns

all public member variables as safe attributes for CFormModel, while it returns all table columns except the primary key as safe attributes for CActiveRecord. We may override this method to limit safe attributes according to scenarios. For example, a user model may contain many attributes, but in login scenario we only need to use username and password attributes. We can specify this limit as follows:

```
public function safeAttributes()
{
    return array(
        parent::safeAttributes(),
        'login' => 'username, password',
    );
}
```

More accurately, the return value of the safeAttributes method should be of the following structure:

If the model is not scenario-sensitive (i.e., it is only used in one scenario, or all scenarios share the same set of safe attributes), the return value can be simplified as a single string:

```
'attr1, attr2, ...'
```

For data entries that are not safe, we need to assign them to the corresponding attributes using individual assign statements, like the following:

```
$model->permission='admin';
$model->id=1;
```

3.2.4 Triggering Validation

Once a model is populated with user-submitted data, we can call CModel::validate() to trigger the data validation process. The method returns a value indicating whether the validation is successful or not. For CActiveRecord model, validation may also be automatically triggered when we call its CActiveRecord::save() method.

When we call CModel::validate(), we may specify a scenario parameter. Only the validation rules that apply to the specified scenario will be executed. A validation rule applies to a scenario if the on option of the rule is not set or contains the specified scenario name. If we do not specify the scenario when calling CModel::validate(), only those rules whose on option is not set will be executed.

For example, we execute the following statement to perform the validation when registering a user:

```
$model->validate('register');
```

We may declare the validation rules in the form model class as follows,

```
public function rules()
{
    return array(
        array('username, password', 'required'),
        array('password_repeat', 'required', 'on'=>'register'),
        array('password', 'compare', 'on'=>'register'),
    );
}
```

As a result, the first rule will be applied in all scenarios, while the next two rules will only be applied in the register scenario.

Note: scenario-based validation has been available since version 1.0.1.

3.2.5 Retrieving Validation Errors

We can use CModel::hasErrors() to check if there is any validation error, and if yes, we can use CModel::getErrors() to obtain the error messages. Both methods can be used for all attributes or an individual attribute.

3.2.6 Attribute Labels

When designing a form, we often need to display a label for each input field. The label tells a user what kind of information he is expected to enter into the field. Although we can hardcode a label in a view, it would offer more flexibility and convenience if we specify it in the corresponding model.

By default, CModel will simply return the name of an attribute as its label. This can be customized by overriding the attributeLabels() method. As we will see in the following subsections, specifying labels in the model allows us to create a form more quickly and powerful.

3.3 Creating Action

Once we have a model, we can start to write logic that is needed to manipulate the model. We place this logic inside a controller action. For the login form example, the following code is needed:

In the above, we first create a LoginForm instance; if the request is a POST request (meaning the login form is submitted), we populate \$form with the submitted data \$_POST['LoginForm']; we then validate the input and if successful, redirect the user browser to the page that previously needed authentication. If the validation fails, or if the action is initially accessed, we render the login view whose content is to be described in the next subsection.

Tip: In the login action, we use \$this->user->returnUrl to get the URL of the page that previously needed authentication. This is because CController has a property named user which is an CWebUser (or its child class) instance representing user session information (e.g. username, status). For more details, see Authentication and Authorization.

Let's pay special attention to the following PHP statement that appears in the login action:

```
$form->attributes=$_POST['LoginForm'];
```

As we described in Securing Attribute Assignments, this line of code populates the model with the user submitted data. The attributes property is defined by CModel which expects an array of name-value pairs and assigns each value to the corresponding model attribute. So if \$_POST['LoginForm'] gives us such an array, the above code would be equivalent to the following lengthy one (assuming every needed attribute is present in the array):

```
$form->username=$_POST['LoginForm']['username'];
$form->password=$_POST['LoginForm']['password'];
$form->rememberMe=$_POST['LoginForm']['rememberMe'];
```

Note: In order to let \$_POST['LoginForm'] to give us an array instead of a string, we stick to a convention when naming input fields in the view. In particular, for an input field corresponding to attribute a of model class C, we name it as C[a]. For example, we would use LoginForm[username] to name the input field corresponding to the username attribute.

The remaining task now is to create the login view which should contain an HTML form with the needed input fields.

3.4 Creating Form

Writing the login view is straightforward. We start with a form tag whose action attribute should be the URL of the login action described previously. We then insert labels and input fields for the attributes declared in the LoginForm class. At the end we insert a submit button which can be clicked by users to submit the form. All these can be done in pure HTML code.

Yii provides a few helper classes to facilitate view composition. For example, to create a text input field, we can call CHtml::textField(); to create a drop-down list, call CHtml::dropDownList().

Info: One may wonder what is the benefit of using helpers if they require similar amount of code when compared with plain HTML code. The answer is that the helpers can provide more than just HTML code. For example, the following code would generate a text input field which can trigger form submission if its value is changed by users.

```
CHtml::textField($name,$value,array('submit'=>''));
```

It would otherwise require writing clumsy JavaScript everywhere.

In the following, we use CHtml to create the login form. We assume that the variable \$user represents LoginForm instance.

```
<div class="yiiForm">
<?php echo CHtml::form(); ?>
<?php echo CHtml::errorSummary($user); ?>
<div class="simple">
<?php echo CHtml::activeLabel($user,'username'); ?>
<?php echo CHtml::activeTextField($user,'username') ?>
</div>
<div class="simple">
<?php echo CHtml::activeLabel($user,'password'); ?>
<?php echo CHtml::activePasswordField($user,'password')</pre>
</div>
<div class="action">
<?php echo CHtml::activeCheckBox($user,'rememberMe'); ?>
Remember me next time<br/>
<?php echo CHtml::submitButton('Login'); ?>
</div>
</form>
</div><!-- yiiForm -->
```

The above code generates a more dynamic form. For example, CHtml::activeLabel() generates a label associated with the specified model attribute. If the attribute has an

input error, the label's CSS class will be changed to error, which changes the appearance of the label with appropriate CSS styles. Similarly, CHtml::activeTextField() generates a text input field for the specified model attribute and changes its CSS class upon any input error. For more details about using CHtml, see Using Helpers.

If we use the CSS style file form.css provided by the yiic script, the generated form would be like the following:

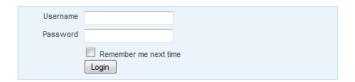

Figure 3.1: The login page

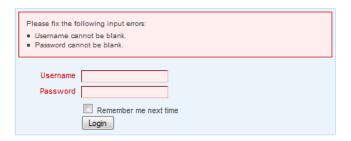

Figure 3.2: The login with error page

3.5 Collecting Tabular Input

Sometimes we want to collect user input in a batch mode. That is, the user can enter the information for multiple model instances and submit them all at once. We call this *tabular input* because the input fields are often presented in an HTML table.

To work with tabular input, we first need to create or populate an array of model instances, depending on whether we are inserting or updating the data. We then retrieve the user input data from the \$_POST variable and assign it to each model. A slight difference from single model input is that we retrieve the input data using \$_POST['ModelClass'][\$i] instead of \$_POST['ModelClass'].

```
public function actionBatchUpdate()
{
    // retrieve items to be updated in a batch mode
```

Having the action ready, we need to work on the batchUpdate view to display the input fields in an HTML table.

Note in the above that we use "name[\$i]" instead of "name" as the second parameter when calling CHtml::activeTextField.

If there is anything validation error, the corresponding input fields will be highlighted automatically, just like the single model input we described earlier on.

Working with Databases

4.1 Working with Database

Yii provides powerful support for database programming. Built on top of the PHP Data Objects (PDO) extension, Yii Data Access Objects (DAO) enables accessing to different database management systems (DBMS) in a single uniform interface. Applications developed using Yii DAO can be easily switched to use a different DBMS without the need to modify the data accessing code. Yii Active Record (AR), implemented as a widely adopted Object-Relational Mapping (ORM) approach, further simplifies database programming. Representing a table in terms of a class and a row an instance, Yii AR eliminates the repetitive task of writing those SQL statements that mainly deal with CRUD (create, read, update and delete) operations.

Although Yii DAO and AR can handle nearly all database-related tasks, you can still use your own database libraries in your Yii application. As a matter of fact, Yii framework is carefully designed to be used together with other third-party libraries.

4.2 Data Access Objects (DAO)

Data Access Objects (DAO) provides a generic API to access data stored in different database management systems (DBMS). As a result, the underlying DBMS can be changed to a different one without requiring change of the code which uses DAO to access the data.

Yii DAO is built on top of PHP Data Objects (PDO) which is an extension providing unified data access to many popular DBMS, such as MySQL, PostgreSQL. Therefore, to use Yii DAO, the PDO extension and the specific PDO database driver (e.g. PDO_MYSQL) have to be installed.

Yii DAO mainly consists of the following four classes:

• CDbConnection: represents a connection to a database.

- CDbCommand: represents an SQL statement to execute against a database.
- CDbDataReader: represents a forward-only stream of rows from a query result set.
- CDbTransaction: represents a DB transaction.

In the following, we introduce the usage of Yii DAO in different scenarios.

4.2.1 Establishing Database Connection

To establish a database connection, create a CDbConnection instance and activate it. A data source name (DSN) is needed to specify the information required to connect to the database. A username and password may also be needed to establish the connection. An exception will be raised in case an error occurs during establishing the connection (e.g. bad DSN or invalid username/password).

```
$connection=new CDbConnection($dsn,$username,$password);
// establish connection. You may try...catch possible exceptions
$connection->active=true;
.....
$connection->active=false; // close connection
```

The format of DSN depends on the PDO database driver in use. In general, a DSN consists of the PDO driver name, followed by a colon, followed by the driver-specific connection syntax. See PDO documentation for complete information. Below is a list of commonly used DSN formats:

- SQLite: sqlite:/path/to/dbfile
- $\bullet \ \mathrm{MySQL} \hbox{:} \ \mathtt{mysql:host=localhost;dbname=testdb} \\$
- PostgreSQL: pgsql:host=localhost;port=5432;dbname=testdb

Because CDbConnection extends from CApplicationComponent, we can also use it as an application component. To do so, configure in a db (or other name) application component in the application configuration as follows,

```
'class'=>'CDbConnection',
'connectionString'=>'mysql:host=localhost;dbname=testdb',
'username'=>'root',
'password'=>'password',
),
),
```

We can then access the DB connection via Yii::app()->db which is already activated automatically, unless we explictly configure CDbConnection::autoConnect to be false. Using this approach, the single DB connection can be shared in multiple places in our code.

4.2.2 Executing SQL Statements

Once a database connection is established, SQL statements can be executed using CDb-Command. One creates a CDbCommand instance by calling CDbConnection::createCommand() with the specified SQL statement:

```
$command=$connection->createCommand($sql);
// if needed, the SQL statement may be updated as follows:
// $command->text=$newSQL;
```

A SQL statement is executed via CDbCommand in one of the following two ways:

- execute(): performs a non-query SQL statement, such as INSERT, UPDATE and DELETE. If successful, it returns the number of rows that are affected by the execution.
- query(): performs an SQL statement that returns rows of data, such as SELECT. If successful, it returns a CDbDataReader instance from which one can traverse the resulting rows of data. For convenience, a set of queryXXX() methods are also implemented which directly return the query results.

An exception will be raised if an error occurs during the execution of SQL statements.

```
$rowCount=$command->execute();  // execute the non-query SQL
$dataReader=$command->query();  // execute a query SQL
$rows=$command->queryAll();  // query and return all rows of result
$row=$command->queryRow();  // query and return the first row of result
$column=$command->queryColumn();  // query and return the first column of result
$value=$command->queryScalar();  // query and return the first field in the first row
```

4.2.3 Fetching Query Results

After CDbCommand::query() generates the CDbDataReader instance, one can retrieve rows of resulting data by calling CDbDataReader::read() repeatedly. One can also use CDbDataReader in PHP's foreach language construct to retrieve row by row.

```
$dataReader=$command->query();
// calling read() repeatedly until it returns false
while(($row=$dataReader->read())!==false) { ... }
// using foreach to traverse through every row of data
foreach($dataReader as $row) { ... }
// retrieving all rows at once in a single array
$rows=$dataReader->readAll();
```

Note: Unlike query(), all queryXXX() methods return data directly. For example, queryRow() returns an array representing the first row of the querying result.

4.2.4 Using Transactions

When an application executes a few queries, each reading and/or writing information in the database, it is important to be sure that the database is not left with only some of the queries carried out. A transaction, represented as a CDbTransaction instance in Yii, may be initiated in this case:

- Begin the transaction.
- Execute queries one by one. Any updates to the database are not visible to the outside world.
- Commit the transaction. Updates become visible if the transaction is successful.
- If one of the queries fails, the entire transaction is rolled back.

The above workflow can be implemented using the following code:

```
$transaction=$connection->beginTransaction();
try
{
    $connection->createCommand($sql1)->execute();
    $connection->createCommand($sql2)->execute();
    //.... other SQL executions
```

```
$transaction->commit();
}
catch(Exception $e) // an exception is raised if a query fails will be raised
{
    $transaction->rollBack();
}
```

4.2.5 Binding Parameters

To avoid SQL injection attacks and to improve performance of executing repeatedly used SQL statements, one can "prepare" an SQL statement with optional parameter placeholders that are to be replaced with the actual parameters during the parameter binding process.

The parameter placeholders can be either named (represented as unique tokens) or unnamed (represented as question marks). Call CDbCommand::bindParam() or CDbCommand::bindValue() to replace these placeholders with the actual parameters. The parameters do not need to be quoted: the underlying database driver does it for you. Parameter binding must be done before the SQL statement is executed.

```
// an SQL with two placeholders ":username" and ":email"
$sql="INSERT INTO users(username, email) VALUES(:username,:email)";
$command=$connection->createCommand($sql);
// replace the placeholder ":username" with the actual username value
$command->bindParam(":username",$username,PDO::PARAM_STR);
// replace the placeholder ":email" with the actual email value
$command->bindParam(":email",$email,PDO::PARAM_STR);
$command->execute();
// insert another row with a new set of parameters
$command->bindParam(":username",$username2,PDO::PARAM_STR);
$command->bindParam(":email",$email2,PDO::PARAM_STR);
$command->execute();
```

The methods bindParam() and bindValue() are very similar. The only difference is that the former binds a parameter with a PHP variable reference while the latter with a value. For parameters that represent large block of data memory, the former is preferred for performance consideration.

For more details about binding parameters, see the relevant PHP documentation.

4.2.6 Binding Columns

When fetching query results, one can also bind columns with PHP variables so that they are automatically populated with the latest data each time a row is fetched.

```
$sql="SELECT username, email FROM users";
$dataReader=$connection->createCommand($sql)->query();
// bind the 1st column (username) with the $username variable
$dataReader->bindColumn(1,$username);
// bind the 2nd column (email) with the $email variable
$dataReader->bindColumn(2,$email);
while($dataReader->read()!==false)
{
    // $username and $email contain the username and email in the current row
}
```

4.3 Active Record

Although Yii DAO can handle virtually any database-related task, chances are that we would spend 90% of our time in writing some SQL statements which perform the common CRUD (create, read, update and delete) operations. It is also difficult to maintain our code when they are mixed with SQL statements. To solve these problems, we can use Active Record.

Active Record (AR) is a popular Object-Relational Mapping (ORM) technique. Each AR class represents a database table (or view) whose attributes are represented as the AR class properties, and an AR instance represents a row in that table. Common CRUD operations are implemented as AR methods. As a result, we can access our data in a more object-oriented way. For example, we can use the following code to insert a new row to the Post table:

```
$post=new Post;
$post->title='sample post';
$post->content='post body content';
$post->save();
```

In the following we describe how to set up AR and use it to perform CRUD operations. We will show how to use AR to deal with database relationships in the next section. For simplicity, we use the following database table for our examples in this section.

```
CREATE TABLE Post (
   id INTEGER NOT NULL PRIMARY KEY AUTOINCREMENT,
   title VARCHAR(128) NOT NULL,
   content TEXT NOT NULL,
   createTime INTEGER NOT NULL
);
```

4.3 Active Record 55

Note: AR is not meant to solve all database-related tasks. It is best used for modeling database tables in PHP constructs and performing queries that do not involve complex SQLs. Yii DAO should be used for those complex scenarios.

4.3.1 Establishing DB Connection

AR relies on a DB connection to perform DB-related operations. By default, it assumes that the db application component gives the needed CDbConnection instance which serves as the DB connection. The following application configuration shows an example:

```
return array(
    'components'=>array(
        'db'=>array(
          'class'=>'system.db.CDbConnection',
          'connectionString'=>'sqlite:path/to/dbfile',
          // turn on schema caching to improve performance
          // 'schemaCachingDuration'=>3600,
        ),
    ),
);
```

Tip: Because Active Record relies on the metadata about tables to determine the column information, it takes time to read the metadata and analyze it. If the schema of your database is less likely to be changed, you should turn on schema caching by configuring the CDbConnection::schemaCachingDuration property to be a value greater than 0.

Support for AR is limited by DBMS. Currently, only the following DBMS are supported:

- MySQL 4.1 or later
- PostgreSQL 7.3 or later
- SQLite 2 and 3

If you want to use an application component other than db, or if you want to work with multiple databases using AR, you should override CActiveRecord::getDbConnection(). The CActiveRecord class is the base class for all AR classes.

Tip: There are two ways to work with multiple databases in AR. If the schemas of the databases are different, you may create different base AR classes with different implementation of getDbConnection(). Otherwise, dynamically changing the static variable CActiveRecord::db is a better idea.

4.3.2 Defining AR Class

To access a database table, we first need to define an AR class by extending CActiveRecord. Each AR class represents a single database table, and an AR instance represents a row in that table. The following example shows the minimal code needed for the AR class representing the Post table.

```
class Post extends CActiveRecord
{
    public static function model($className=__CLASS__)
    {
        return parent::model($className);
    }
}
```

Tip: Because AR classes are often referenced in many places, we can import the whole directory containing the AR class, instead of including them one by one. For example, if all our AR class files are under protected/models, we can configure the application as follows:

```
return array(
   'import'=>array(
        'application.models.*',
   ),
);
```

By default, the name of the AR class is the same as the database table name. Override the tableName() method if they are different. The model() method is declared as such for every AR class (to be explained shortly).

Column values of a table row can be accessed as properties of the corresponding AR class instance. For example, the following code sets the title column (attribute):

```
$post=new Post;
$post->title='a sample post';
```

4.3 Active Record 57

Although we never explicitly declare the title property in the Post class, we can still access it in the above code. This is because title is a column in the Post table, and CActiveRecord makes it accessible as a property with the help of the PHP __get() magic method. An exception will be thrown if we attempt to access a non-existing column in the same way.

Info: For better readability, we suggest naming database tables and columns in camel case. In particular, table names are formed by capitalizing each word in the name and joining them without spaces; column names are similar to table names except their first letter is in lower case. For example, we use Post to name the table storing posts; and we use createTime to name the table's primary key column. This makes tables look more like class types and columns like variables.

4.3.3 Creating Record

To insert a new row into a database table, we create a new instance of the corresponding AR class, set its properties associated with the table columns, and call the save() method to finish the insertion.

```
$post=new Post;
$post->title='sample post';
$post->content='content for the sample post';
$post->createTime=time();
$post->save();
```

If the table's primary key is auto-incremental, after the insertion the AR instance will contain an updated primary key. In the above example, the id property will reflect the primary key value of the newly inserted post, even though we never change it explicitly.

If a column is defined with some static default value (e.g. a string, a number) in the table schema, the corresponding property in the AR instance will automatically has such a value after the instance is created. One way to change this default value is by explicitly declaring the property in the AR class:

```
class Post extends CActiveRecord
{
    public $title='please enter a title';
    .....
}

$post=new Post;
echo $post->title; // this would display: please enter a title
```

Starting from version 1.0.2, an attribute can be assigned a value of CDbExpression type before the record is saved (either insertion or updating) to the database. For example, in order to save a timestamp returned by the MySQL NOW() function, we can use the following code:

```
$post=new Post;
$post->createTime=new CDbExpression('NOW()');
// $post->createTime='NOW()'; will not work because
// 'NOW()' will be treated as a string
$post->save();
```

4.3.4 Reading Record

To read data in a database table, we call one of the find methods as follows.

```
// find the first row satisfying the specified condition
$post=Post::model()->find($condition,$params);
// find the row with the specified primary key
$post=Post::model()->findByPk($postID,$condition,$params);
// find the row with the specified attribute values
$post=Post::model()->findByAttributes($attributes,$condition,$params);
// find the first row using the specified SQL statement
$post=Post::model()->findBySql($sql,$params);
```

In the above, we call the find method with Post::model(). Remember that the static method model() is required for every AR class. The method returns an AR instance that is used to access class-level methods (something similar to static class methods) in an object context.

If the find method finds a row satisfying the query conditions, it will return a Post instance whose properties contain the corresponding column values of the table row. We can then read the loaded values like we do with normal object properties, for example, echo \$post->title;.

The find method will return null if nothing can be found in the database with the given query condition.

When calling find, we use \$condition and \$params to specify query conditions. Here \$condition can be string representing the WHERE clause in a SQL statement, and \$params is an array of parameters whose values should be bound to the placeholders in \$condition. For example,

```
// find the row with postID=10
$post=Post::model()->find('postID=:postID', array(':postID'=>10));
```

4.3 Active Record 59

We can also use \$condition to specify more complex query conditions. Instead of a string, we let \$condition be a CDbCriteria instance, which allows us to specify conditions other than the WHERE clause. For example,

```
$criteria=new CDbCriteria;
$criteria->select='title'; // only select the 'title' column
$criteria->condition='postID=:postID';
$criteria->params=array(':postID'=>10);
$post=Post::model()->find($criteria); // $params is not needed
```

Note, when using CDbCriteria as query condition, the \$params parameter is no longer needed since it can be specified in CDbCriteria, as shown above.

An alternative way to CDbCriteria is passing an array to the find method. The array keys and values correspond to the criteria's property name and value, respectively. The above example can be rewritten as follows,

```
$post=Post::model()->find(array(
    'select'=>'title',
    'condition'=>'postID=:postID',
    'params'=>array(':postID'=>10),
));
```

Info: When a query condition is about matching some columns with the specified values, we can use findByAttributes(). We let the \$attributes parameters be an array of the values indexed by the column names. In some frameworks, this task can be achieved by calling methods like findByNameAndTitle. Although this approach looks attractive, it often causes confusion, conflict and issues like case-sensitivity of column names.

When multiple rows of data matching the specified query condition, we can bring them in all together using the following findAll methods, each of which has its counterpart find method, as we already described.

```
// find all rows satisfying the specified condition
$posts=Post::model()->findAll($condition,$params);
// find all rows with the specified primary keys
$posts=Post::model()->findAllByPk($postIDs,$condition,$params);
// find all rows with the specified attribute values
$posts=Post::model()->findAllByAttributes($attributes,$condition,$params);
// find all rows using the specified SQL statement
$posts=Post::model()->findAllBySql($sql,$params);
```

If nothing matches the query condition, findAll would return an empty array. This is different from find who would return null if nothing is found.

Besides the find and findAll methods described above, the following methods are also provided for convenience:

```
// get the number of rows satisfying the specified condition
$n=Post::model()->count($condition,$params);
// get the number of rows using the specified SQL statement
$n=Post::model()->countBySql($sql,$params);
// check if there is at least a row satisfying the specified condition
$exists=Post::model()->exists($condition,$params);
```

4.3.5 Updating Record

After an AR instance is populated with column values, we can change them and save them back to the database table.

```
$post=Post::model()->findByPk(10);
$post->title='new post title';
$post->save(); // save the change to database
```

As we can see, we use the same save() method to perform insertion and updating operations. If an AR instance is created using the new operator, calling save() would insert a new row into the database table; if the AR instance is the result of some find or findAll method call, calling save() would update the existing row in the table. In fact, we can use CActiveRecord::isNewRecord to tell if an AR instance is new or not.

It is also possible to update one or several rows in a database table without loading them first. AR provides the following convenient class-level methods for this purpose:

```
// update the rows matching the specified condition
Post::model()->updateAll($attributes,$condition,$params);
// update the rows matching the specified condition and primary key(s)
Post::model()->updateByPk($pk,$attributes,$condition,$params);
// update counter columns in the rows satisfying the specified conditions
Post::model()->updateCounters($counters,$condition,$params);
```

In the above, \$attributes is an array of column values indexed by column names; \$counters is an array of incremental values indexed by column names; and \$condition and \$params are as described in the previous subsection.

4.3 Active Record 61

4.3.6 Deleting Record

We can also delete a row of data if an AR instance has been populated with this row.

```
$post=Post::model()->findByPk(10); // assuming there is a post whose ID is 10
$post->delete(); // delete the row from the database table
```

Note, after deletion, the AR instance remains unchanged, but the corresponding row in the database table is already gone.

The following class-level methods are provided to delete rows without the need of loading them first:

```
// delete the rows matching the specified condition
Post::model()->deleteAll($condition,$params);
// delete the rows matching the specified condition and primary key(s)
Post::model()->deleteByPk($pk,$condition,$params);
```

4.3.7 Data Validation

When inserting or updating a row, we often need to check if the column values comply to certain rules. This is especially important if the column values are provided by end users. In general, we should never trust anything coming from the client side.

AR performs data validation automatically when save() is being invoked. The validation is based on the rules specified by in the rules() method of the AR class. For more details about how to specify validation rules, refer to the Declaring Validation Rules section. Below is the typical workflow needed by saving a record:

```
if($post->save())
{
    // data is valid and is successfully inserted/updated
}
else
{
    // data is invalid. call getErrors() to retrieve error messages
}
```

When the data for inserting or updating is submitted by end users in an HTML form, we need to assign them to the corresponding AR properties. We can do so like the following:

```
$post->title=$_POST['title'];
$post->content=$_POST['content'];
$post->save();
```

If there are many columns, we would see a long list of such assignments. This can be alleviated by making use of the attributes property as shown below. More details can be found in the Securing Attribute Assignments section and the Creating Action section.

```
// assume $_POST['Post'] is an array of column values indexed by column names
$post->attributes=$_POST['Post'];
$post->save();
```

4.3.8 Comparing Records

Like table rows, AR instances are uniquely identified by their primary key values. Therefore, to compare two AR instances, we merely need to compare their primary key values, assuming they belong to the same AR class. A simpler way is to call CActiveRecord::equals(), however.

Info: Unlike AR implementation in other frameworks, Yii supports composite primary keys in its AR. A composite primary key consists of two or more columns. Correspondingly, the primary key value is represented as an array in Yii. The primaryKey property gives the primary key value of an AR instance.

4.3.9 Customization

CActiveRecord provides a few placeholder methods that can be overridden in child classes to customize its workflow.

- before Validate and after Validate: these are invoked before and after validation is performed.
- beforeSave and afterSave: these are invoked before and after saving an AR instance.
- beforeDelete and afterDelete: these are invoked before and after an AR instance is deleted.
- afterConstruct: this is invoked for every AR instance created using the new operator.
- afterFind: this is invoked for every AR instance created as a result of query.

4.3.10 Using Transaction with AR

Every AR instance contains a property named dbConnection which is a CDbConnection instance. We thus can use the transaction feature provided by Yii DAO if it is desired when working with AR:

```
$model=Post::model();
$transaction=$model->dbConnection->beginTransaction();
try
{
    // find and save are two steps which may be intervened by another request
    // we therefore use a transaction to ensure consistency and integrity
    $post=$model->findByPk(10);
    $post->title='new post title';
    $post->save();
    $transaction->commit();
}
catch(Exception $e)
{
    $transaction->rollBack();
}
```

4.4 Relational Active Record

We have already seen how to use Active Record (AR) to select data from a single database table. In this section, we describe how to use AR to join several related database tables and bring back the joint data set.

In order to use relational AR, it is required that primary-foreign key relationships are well defined between tables that need to be joined. AR relies on the metadata about these relationships to determine how to join the tables.

Note: Starting from version 1.0.1, you can use relational AR even if you do not define any foreign key constraints in your database.

For simplicity, we will use the database schema shown in the following entity-relationship (ER) diagram to illustrate examples in this section.

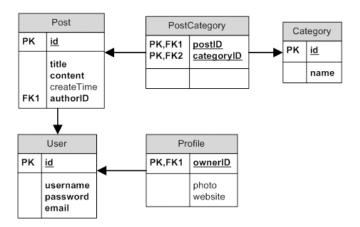

Figure 4.1: ER Diagram

Info: Support for foreign key contraints varies in different DBMS.

SQLite does not support foreign key constraints, but you can still declare the constraints when creating tables. AR can exploit these declarations to correctly support relational queries.

MySQL supports foreign key constraints with InnoDB engine, but not with My-ISAM. It is thus recommended that you use InnoDB for your MySQL database. When using MyISAM, you may exploit the following trick so that you can perform relational queries using AR:

```
CREATE TABLE Foo

(
   id INTEGER NOT NULL PRIMARY KEY
);

CREATE TABLE bar
(
   id INTEGER NOT NULL PRIMARY KEY,
   fooID INTEGER

        COMMENT 'CONSTRAINT FOREIGN KEY (fooID) REFERENCES Foo(id)'
);
```

In the above, we use COMMENT keyword to describe the foreign key constraint which can be read by AR to recognize the described relationship.

4.4.1 Declaring Relationship

Before we use AR to perform relational query, we need to let AR know how one AR class is related with another.

Relationship between two AR classes is directly associated with the relationship between the database tables represented by the AR classes. From database point of view, a relationship between two tables A and B has three types: one-to-many (e.g. User and Post), one-to-one (e.g. User and Profile) and many-to-many (e.g. Category and Post). In AR, there are four types of relationships:

- BELONGS_TO: if the relationship between table A and B is one-to-many, then B belongs to A (e.g. Post belongs to User);
- HAS_MANY: if the relationship between table A and B is one-to-many, then A has many B (e.g. User has many Post);
- HAS_ONE: this is special case of HAS_MANY where A has at most one B (e.g. User has at most one Profile);
- MANY_MANY: this corresponds to the many-to-many relationship in database. An associative table is needed to break a many-to-many relationship into one-to-many relationships, as most DBMS do not support many-to-many relationship directly. In our example database schema, the PostCategory serves for this purpose. In AR terminology, we can explain MANY_MANY as the combination of BELONGS_TO and HAS_MANY. For example, Post belongs to many Category and Category has many Post.

Declaring relationship in AR involves overriding the relations() method of CActiveRecord. The method returns an array of relationship configurations. Each array element represents a single relationship with the following format:

```
'VarName' => array('RelationType', 'ClassName', 'ForeignKey', ...additional options)
```

where VarName is the name of the relationship; RelationType specifies the type of the relationship, which can be one of the four constants: self::BELONGS_TO, self::HAS_ONE, self::HAS_MANY and self::MANY_MANY; ClassName is the name of the AR class related to this AR class; and ForeignKey specifies the foreign key(s) involved in the relationship. Additional options can be specified at the end for each relationship (to be described later).

The following code shows how we declare the relationships for the User and Post classes.

```
class Post extends CActiveRecord
{
    public function relations()
    {
        return array(
```

Info: A foreign key may be composite, consisting of two or more columns. In this case, we should concatenate the names of the foreign key columns and separate them with space or comma. For MANY_MANY relationship type, the associative table name must also be specified in the foreign key. For example, the categories relationship in Post is specified with the foreign key PostCategory(postID, categoryID).

The declaration of relationships in an AR class implicitly adds a property to the class for each relationship. After a relational query is performed, the corresponding property will be populated with the related AR instance(s). For example, if \$author represents a User AR instance, we can use \$author->posts to access its related Post instances.

4.4.2 Performing Relational Query

The simplest way of performing relational query is by reading a relational property of an AR instance. If the property is not accessed previously, a relational query will be initiated, which joins the two related tables and filters with the primary key of the current AR instance. The query result will be saved to the property as instance(s) of the related AR class. This is known as the *lazy loading* approach, i.e., the relational query is performed only when the related objects are initially accessed. The example below shows how to use this approach:

```
// retrieve the post whose ID is 10
$post=Post::model()->findByPk(10);
// retrieve the post's author: a relational query will be performed here
$author=$post->author;
```

Info: If there is no related instance for a relationship, the corresponding property could be either null or an empty array. For BELONGS_TO and HAS_ONE relationships, the result is null; for HAS_MANY and MANY_MANY, it is an empty array.

The lazy loading approach is very convenient to use, but it is not efficient in some scenarios. For example, if we want to access the author information for N posts, using the lazy approach would involve executing N join queries. We should resort to the so-called *eager* loading approach under this circumstance.

The eager loading approach retrieves the related AR instances together with the main AR instance(s). This is accomplished by using the with() method together with one of the find or findAll methods in AR. For example,

```
$posts=Post::model()->with('author')->findAll();
```

The above code will return an array of Post instances. Unlike the lazy approach, the author property in each Post instance is already populated with the related User instance before we access the property. Instead of executing a join query for each post, the eager loading approach brings back all posts together with their authors in a single join query!

We can specify multiple relationship names in the with() method and the eager loading approach will bring them back all in one shot. For example, the following code will bring back posts together with their authors and categories:

```
$posts=Post::model()->with('author','categories')->findAll();
```

We can also do nested eager loading. Instead of a list of relationship names, we pass in a hierarchical representation of relationship names to the with() method, like the following,

```
$posts=Post::model()->with(
    'author.profile',
    'author.posts',
    'categories)->findAll();
```

The above example will bring back all posts together with their author and categories. It will also bring back each author's profile and posts.

Note: The usage of the with() method has been changed since version 1.0.2. Please read the corresponding API documentation carefully.

The AR implementation in Yii is very efficient. When eager loading a hierarchy of related objects involving N HAS_MANY or MANY_MANY relationships, it will take N+1 SQL queries to obtain the needed results. This means it needs to execute 3 SQL queries in the last example because of the posts and categories properties. Other frameworks take a more radical approach by using only one SQL query. At first look, the radical approach seems more efficient because fewer queries are being parsed and executed by DBMS. It is in fact impractical in reality for two reasons. First, there are many repetitive data columns in the result which takes extra time to transmit and process. Second, the number of rows in the result set grows exponentially with the number of tables involved, which makes it simply unmanageable as more relationships are involved.

Since version 1.0.2, you can also enforce the relational query to be done with only one SQL query. Simply append a together() call after with(). For example,

```
$posts=Post::model()->with(
    'author.profile',
    'author.posts',
    'categories')->together()->findAll();
```

The above query will be done in one SQL query. Without calling together, this will need two SQL queries: one joins Post, User and Profile tables, and the other joins User and Post tables.

4.4.3 Relational Query Options

We mentioned that additional options can be specified in relationship declaration. These options, specified as name-value pairs, are used to customize the relational query. They are summarized as below.

- select: a list of columns to be selected for the related AR class. It defaults to '*', meaning all columns. Column names should be disambiguated using aliasToken if they appear in an expression (e.g. COUNT(??.name) AS nameCount).
- condition: the WHERE clause. It defaults to empty. Note, column references need to be disambiguated using aliasToken (e.g. ??.id=10).
- on: the ON clause. The condition specified here will be appended to the joining condition using the AND operator. This option has been available since version 1.0.2.
- order: the ORDER BY clause. It defaults to empty. Note, column references need to be disambiguated using aliasToken (e.g. ??.age DESC).

- with: a list of child related objects that should be loaded together with this object. Note, this is only honored by lazy loading, not eager loading.
- joinType: type of join for this relationship. It defaults to LEFT OUTER JOIN.
- aliasToken: the column prefix placeholder. It will be replaced by the corresponding table alias to disambiguate column references. It defaults to '??.'.
- alias: the alias for the table associated with this relationship. This option has been available since version 1.0.1. It defaults to null, meaning the table alias is automatically generated. This is different from aliasToken in that the latter is just a placeholder and will be replaced by the actual table alias.

In addition, the following options are available for certain relationships during lazy loading:

- group: the GROUP BY clause. It defaults to empty. Note, column references need to be disambiguated using aliasToken (e.g. ??.age). This option only applies to HAS_MANY and MANY_MANY relationships.
- having: the HAVING clause. It defaults to empty. Note, column references need to be disambiguated using aliasToken (e.g. ??.age). This option only applies to HAS_MANY and MANY_MANY relationships. Note: option has been available since version 1.0.1.
- limit: limit of the rows to be selected. This option does NOT apply to BELONGS_TO relation.
- offset: offset of the rows to be selected. This option does NOT apply to BELONGS_TO relation.

Below we modify the posts relationship declaration in the User by including some of the above options:

Now if we access \$author->posts, we would obtain the author's posts sorted according to their creation time in descending order. Each post instance also has its categories loaded.

Info: When a column name appears in two or more tables being joined together, it needs to be disambiguated. This is done by prefixing the column name with its table name. For example, id becomes Team.id. In AR relational queries, however, we do not have this freedom because the SQL statements are automatically generated by AR which systematically gives each table an alias. Therefore, in order to avoid column name conflict, we use a placeholder to indicate the existence of a column which needs to be disambiguated. AR will replace the placeholder with a suitable table alias and properly disambiguate the column.

4.4.4 Dynamic Relational Query Options

Starting from version 1.0.2, we can use dynamic relational query options in both with() and the with option. The dynamic options will overwrite existing options as specified in the relations() method. For example, with the above User model, if we want to use eager loading approach to bring back posts belonging to an author in ascending order (the order option in the relation specification is descending order), we can do the following:

```
User::model()->with(array(
    'posts'=>array('order'=>'??.createTime DESC'),
    'profile',
))->findAll();
```

Caching

5.1 Caching

Caching is a cheap and effective way to improve the performance of a Web application. By storing relatively static data in cache and serving it from cache when requested, we save the time needed to generate the data.

Using cache in Yii mainly involves configuring and accessing a cache application component. The following application configuration specifies a cache component that uses memcache with two cache servers.

When the application is running, the cache component can be accessed via Yii::app()->cache.

Yii provides various cache components that can store cached data in different medium. For example, the CMemCache component encapsulates the PHP memcache extension and uses memory as the medium of cache storage; the CApcCache component encapsulates the PHP APC extension; and the CDbCache component stores cached data in database. The following is a summary of the available cache components:

• CMemCache: uses PHP memcache extension.

72 5. Caching

- CApcCache: uses PHP APC extension.
- CXCache: uses PHP XCache extension. Note, this has been available since version 1.0.1.

• CDbCache: uses a database table to store cached data. By default, it will create and use a SQLite3 database under the runtime directory. You can explicitly specify a database for it to use by setting its connectionID property.

Tip: Because all these cache components extend from the same base class CCache, one can switch to use a different type of cache without modifying the code that uses cache.

Caching can be used at different levels. At the lowest level, we use cache to store a single piece of data, such as a variable, and we call this *data caching*. At the next level, we store in cache a page fragment which is the generated by a portion of a view script. And at the highest level, we store a whole page in cache and serve it from cache as needed.

In the next few subsections, we elaborate how to use cache at these levels.

Note: By definition, cache is a volatile storage medium. It does not ensure the existence of the cached data even if it does not expire. Therefore, do not use cache as a persistent storage (e.g. do not use cache to store session data).

5.2 Data Caching

Data caching is about storing some PHP variable in cache and retrieving it later from cache. For this purpose, the cache component base class CCache provides two methods that are used in most of the time: set() and get().

To store a variable \$value in cache, we choose a unique ID and call set() to store it:

```
Yii::app()->cache->set($id, $value);
```

The cached data will remain in the cache forever unless it is removed because of some caching policy (e.g. caching space is full and the oldest data are removed). To change this behavior, we can also supply an expiration parameter when calling set() so that the data will be removed from the cache after a certain period of time:

```
// keep the value in cache for at most 30 seconds
Yii::app()->cache->set($id, $value, 30);
```

Later when we need to access this variable (in either the same or a different Web request), we call get() with the ID to retrieve it from cache. If the value returned is false, it means the value is not available in cache and we should regenerate it.

```
$value=Yii::app()->cache->get($id);
if($value===false)
{
    // regenerate $value because it is not found in cache
    // and save it in cache for later use:
    // Yii::app()->cache->set($id,$value);
}
```

When choosing the ID for a variable to be cached, make sure the ID is unique among all other variables that may be cached in the application. It is NOT required that the ID is unique across applications because the cache component is intelligent enough to differentiate IDs for different applications.

To remove a cached value from cache, call delete(); and to remove everything from cache, call flush(). Be very careful when calling flush() because it also removes cached data that are from other applications.

```
Tip: Because CCache implements ArrayAccess, a cache component can be used
liked an array. The followings are some examples:

$cache=Yii::app()->cache;
$cache['var1']=$value1; // equivalent to: $cache->set('var1',$value1);
$value2=$cache['var2']; // equivalent to: $value2=$cache->get('var2');
```

5.2.1 Cache Dependency

Besides expiration setting, cached data may also be invalidated according to some dependency changes. For example, if we are caching the content of some file and the file is changed, we should invalidate the cached copy and read the latest content from the file instead of the cache.

We represent a dependency as an instance of CCacheDependency or its child class. We pass the dependency instance along with the data to be cached when calling set().

```
// the value will expire in 30 seconds
```

74 5. Caching

```
// it may also be invalidated earlier if the dependent file is changed
Yii::app()->cache->set($id, $value, 30, new CFileCacheDependency('FileName'));
```

Now if we retrieve \$value from cache by calling get(), the dependency will be evaluated and if it is changed, we will get a false value, indicating the data needs to be regenerated.

Below is a summary of the available cache dependencies:

- CFileCacheDependency: the dependency is changed if the file's last modification time is changed.
- CDirectoryCacheDependency: the dependency is changed if any of the files under the directory and its subdirectories is changed.
- CDbCacheDependency: the dependency is changed if the query result of the specified SQL statement is changed.
- CGlobalStateCacheDependency: the dependency is changed if the value of the specified global state is changed. A global state is a variable that is persistent across multiple requests and multiple sessions in an application. It is defined via CApplication::setGlobalState().
- CChainedCacheDependency: the dependency is changed if any of the dependencies on the chain is changed.

5.3 Fragment Caching

Fragment caching refers to caching a fragment of a page. For example, if a page displays a summary of yearly sale in a table, we can store this table in cache to eliminate the time needed to generate it for each request.

To use fragment caching, we call CController::beginCache() and CController::endCache() in a controller's view script. The two methods mark the beginning and the end of the page content that should be cached, respectively. Like data caching, we need an ID to identify the fragment being cached.

```
...other HTML content...
<?php if($this->beginCache($id)) { ?>
...content to be cached...
<?php $this->endCache(); } ?>
...other HTML content...
```

In the above, if beginCache() returns false, the cached content will be automatically inserted at the place; otherwise, the content inside the if-statement will be executed and be cached when endCache() is invoked.

5.3.1 Caching Options

When calling beginCache(), we can supply an array as the second parameter consisting of caching options to customize the fragment caching. As a matter of fact, the beginCache() and endCache() methods are a convenient wrapper of the COutputCache widget. Therefore, the caching options can be initial values for any properties of COutputCache.

Duration

Perhaps the most commonly option is duration which specifies how long the content can remain valid in cache. It is similar to the expiration parameter of CCache::set(). The following code caches the content fragement for at most one hour:

```
...other HTML content...
<?php if($this->beginCache($id, array('duration'=>3600))) { ?>
...content to be cached...
<?php $this->endCache(); } ?>
...other HTML content...
```

If we do not set the duration, it would default to 60, meaning the cached content will be invalidated after 60 seconds.

Dependency

Like data caching, content fragment being cached can also have dependencies. For example, the content of a post being displayed depends on whether or not the post is modified.

To specify a dependency, we set the dependency option, which can be either an object implementing ICacheDependency or a configuration array that can be used to generate the dependency object. The following code specifies the fragment content depends on the change of lastModified column value:

76 5. Caching

```
...content to be cached...
<?php $this->endCache(); } ?>
...other HTML content...
```

Variation

Content being cached may be variated according to some parameters. For example, the personal profile may look differently to different users. To cache the profile content, we would like the cached copy to be variated according to user IDs. This essentially means that we should use different IDs when calling beginCache().

Instead of asking developers to variate the IDs according to some scheme, COutputCache is built-in with such a feature. Below is a summary.

- varyByRoute: by setting this option to true, the cached content will be variated according to route. Therefore, each combination of the requested controller and action will have a separate cached content.
- varyBySession: by setting this option to true, we can make the cached content to be variated according to session IDs. Therefore, each user session may see different content and they are all served from cache.
- varyByParam: by setting this option to an array of names, we can make the cached content to be variated according to the values of the specified GET parameters. For example, if a page displays the content of a post according to the id GET parameter, we can specify varyByParam to be array('id') so that we can cache the content for each post. Without such variation, we would only be able to cache a single post.

Request Types

Sometimes we want the fragment caching to be enabled only for certain types of request. For example, for a page displaying a form, we only want to cache the form when it is initially requested (via GET request). Any subsequent display (via POST request) of the form should not be cached because the form may contain user input. To do so, we can specify the requestTypes option:

```
...other HTML content...
<?php if($this->beginCache($id, array('requestTypes'=>array('GET')))) { ?>
...content to be cached...
<?php $this->endCache(); } ?>
...other HTML content...
```

5.3.2 Nested Caching

Fragment caching can be nested. That is, a cached fragment is enclosed within a bigger fragment that is also cached. For example, the comments are cached in an inner fragment cache, and they are cached together with the post content in an outer fragment cache.

Different caching options can be set to the nested caches. For example, the inner cache and the outer cache in the above example can be set with different duration values. When the data cached in the outer cache is invalidated, the inner cache may still provide valid inner fragment. However, it is not true vice versa. If the outer cache contains valid data, it will always provide the cached copy, even though the content in the inner cache already expires.

5.4 Page Caching

Page caching refers to caching the content of a whole page. Page caching can occur at different places. For example, by choosing an appropriate page header, the client browser may cache the page being viewed for a limited time. The Web application itself can also store the page content in cache. In this subsection, we focus on this latter approach.

Page caching can be considered as a special case of fragment caching. Because the content of a page is often generated by applying a layout to a view, it will not work if we simply call beginCache() and endCache() in the layout. The reason is because the layout is applied within the CController::render() method AFTER the content view is evaluated.

To cache a whole page, we should skip the execution of the action generating the page content. We can use COutputCache as an action filter to accomplish this task. The following code shows how we configure the cache filter:

```
public function filters()
{
    return array(
```

78 5. Caching

The above filter configuration would make the filter to be applied to all actions in the controller. We may limit it to one or a few actions only by using the plus operator. More details can be found in filter.

Tip: We can use COutputCache as a filter because it extends from CFilterWidget, which means it is both a widget and a filter. In fact, the way a widget works is very similar to a filter: a widget (filter) begins before any enclosed content (action) is evaluated, and the widget (filter) ends after the enclosed content (action) is evaluated.

5.5 Dynamic Content

When using fragment caching or page caching, we often encounter the situation where the whole portion of the output is relatively static except at one or several places. For example, a help page may display static help information with the name of the user currently logged in displayed at the top.

To solve this issue, we can variate the cache content according to the username, but this would be a big waste of our precious cache space since most content are the same except the username. We can also divide the page into several fragments and cache them individually, but this complicates our view and makes our code very complex. A better approach is to use the *dynamic content* feature provided by CController.

A dynamic content means a fragment of output that should not be cached even if it is enclosed within a fragment cache. To make the content dynamic all the time, it has to be generated every time even when the enclosing content is being served from cache. For this reason, we require that dynamic content be generated by some method or function.

We call CController::renderDynamic() to insert dynamic content at the desired place.

```
...fragment content to be cached...
<?php $this->endCache(); } ?>
...other HTML content...
```

In the above, \$callback refers to a valid PHP callback. It can be a string referring to the name of a method in the current controller class or a global function. It can also be an array referring to a class method. Any additional parameters to renderDynamic() will be passed to the callback. The callback should return the dynamic content instead of displaying it.

5. Caching

Chapter 6

Extending Yii

6.1 Overview

Extending Yii is a common activity during development. For example, when you write a new controller, you extend Yii by inheriting its CController class; when you write a new widget, you are extending CWidget or an existing widget class. If the extended code is designed to be reused by third-party developers, we call it an *extension*.

An extension usually serves for a single purpose. In Yii's terms, it can be classified as follows,

- application component
- widget
- controller
- action
- filter
- console command
- validator: a validator is a component class extending CValidator.
- helper: a helper is a class with only static methods. It is like global functions using the class name as their namespace.
- module: a module is a package of several class files and the corresponding asset files. A module often achieves higher level and more advanced functionalities than a single component. For example, we could have a module that provides user management functionalities.

82 6. Extending YII

An extension can also be a component that does not fall into any of the above categories. As a matter of fact, Yii is carefully designed such that nearly every piece of its code can be extended and customized to fit for individual needs.

6.2 Using Extensions

Using an extension usually involves the following three steps:

- 1. Download the extension from Yii's extension repository.
- 2. Unpack the extension under the extensions/xyz subdirectory of application base directory, where xyz is the name of the extension.
- 3. Import, configure and use the extension.

Each extension has a name that uniquely identifies it among all extensions. Given an extension named as xyz, we can always use the path alias application.extensions.xyz to locate its base directory which contains all files of xyz.

Different extensions have different requirements about importing, configuration and usage. In the following, we summarize common usage scenarios about extensions, according to their categorization described in the overview.

6.2.1 Application Component

To use an application component, we first need to change the application configuration by adding a new entry to its components property, like the following:

Then, we can access the component at any place using Yii::app()->xyz. The component will be lazily created (that is, created when it is accessed for the first time) unless we list it the preload property.

6.2.2 Widget

Widgets are mainly used in views. Given a widget class XyzClass belonging to the xyz extension, we can use it in a view as follows,

6.2.3 Action

Actions are used by a controller to respond specific user requests. Given an action class XyzClass belonging to the xyz extension, we can use it by overriding the CController::actions method in our controller class:

Then, the action can be accessed via route test/xyz.

6.2.4 Filter

Filters are also used by a controller. Their mainly pre- and post-process the user request when it is handled by an action. Given a filter class XyzClass belonging to the xyz

84 6. Extending YII

extension, we can use it by overriding the CController::filters method in our controller class:

In the above, we can use plus and minus operators in the first array element to apply the filter to limited actions only. For more details, please refer to the documentation of CController.

6.2.5 Controller

A controller provides a set of actions that can be requested by users. In order to use a controller extension, we need to configure the CWebApplication::controllerMap property in the application configuration:

```
return array(
    'controllerMap'=>array(
        'xyz'=>array(
        'class'=>'application.extensions.xyz.XyzClass',
        'property1'=>'value1',
        'property2'=>'value2',
     ),
     // other controllers
    ),
);
```

Then, an action a in the controller can be accessed via route xyz/a.

6.2.6 Validator

A validator is mainly used in a model class (one that extends from either CFormModel or CActiveRecord). Given a validator class XyzClass belonging to the xyz extension, we can

use it by overriding the CModel::rules method in our model class:

6.2.7 Console Command

A console command extension usually enhances the yiic tool with an additional command. Given a console command XyzClass belonging to the xyz extension, we can use it by configuring the configuration for the console application:

```
return array(
    'commandMap'=>array(
    'xyz'=>array(
        'class'=>'application.extensions.xyz.XyzClass',
        'property1'=>'value1',
        'property2'=>'value2',
    ),
    // other commands
   ),
);
```

Then, we can use the yiic tool is equipped with an additional command xyz.

Note: A console application usually uses a configuration file that is different from the one used by a Web application. If an application is created using yiic webapp command, then the configuration file for the console application protected/yiic is protected/config/console.php, while the configuration file for the Web application is protected/config/main.php.

86 6. Extending YII

6.2.8 Module

A module typically consists of more than one class files and is often a mix of the above extension types. Therefore, you should follow the corresponding instructions to use a module.

6.2.9 Generic Component

To use a generic component, we first need to include its class file by using

```
Yii::import('application.extensions.xyz.XyzClass');
```

Then, we can either create an instance of the class, configure its properties, and call its methods. We may also extend it to create new child classes.

6.3 Creating Extensions

Because an extension is meant to be used by third-party developers, it takes some additional efforts to create it. The followings are some general guidelines:

- An extension should be self-contained. That is, its external dependency should be minimal. It would be a headache for its users if an extension requires installation of additional packages, classes or resource files.
- Files belonging to an extension should be organized under the same directory whose name is the extension name
- Classes in an extension should be prefixed with some letter(s) to avoid naming conflict with classes in other extensions.
- An extension should come with detailed installation and API documentation. This
 would reduce the time and effort needed by other developers when they use the
 extension.
- An extension should be using an appropriate license. If you want to make your extension to be used by both open-source and closed-source projects, you may consider using licenses such as BSD, MIT, etc., but not GPL as it requires its derived code to be open-source as well.

In the following, we describe how to create a new extension, according to its categorization as described in overview. These descriptions also apply when you are creating a component mainly used in your own projects.

6.3.1 Application Component

An application component should implement the interface IApplicationComponent or extend from CApplicationComponent. The main method needed to be implemented is IApplicationComponent::init in which the component performs some initialization work. This method is invoked after the component is created and the initial property values (specified in application configuration) are applied.

By default, an application component is created and initialized only when it is accessed for the first time during request handling. If an application component needs to be created right after the application instance is created, it should require the user to list its ID in the CApplication::preload property.

6.3.2 Widget

A widget should extend from CWidget or its child classes.

The easiest way of creating a new widget is extending an existing widget and overriding its methods or changing its default property values. For example, if you want to use a nicer CSS style for CTabView, you could configure its CTabView::cssFile property when using the widget. You can also extend CTabView as follows so that you no longer need to configure the property when using the widget.

In the above, we override the CWidget::init method and assign to CTabView::cssFile the URL to our new default CSS style if the property is not set. We put the new CSS style file under the same directory containing the MyTabView class file so that they can be packaged as an extension. Because the CSS style file is not Web accessible, we need to publish as an asset.

To create a new widget from scratch, we mainly need to implement two methods: CWidget::init and CWidget::run. The first method is called when we use \$this->beginWidget to

88 6. Extending YII

insert a widget in a view, and the second method is called when we call \$this->endWidget. If we want to capture and process the content displayed between these two method invocations, we can start output buffering in CWidget::init and retrieve the buffered output in CWidget::run for further processing.

A widget often involves including CSS, JavaScript or other resource files in the page that uses the widget. We call these files assets because they stay together with the widget class file and are usually not accessible by Web users. In order to make these files Web accessible, we need to publish them using CWebApplication::assetManager, as shown in the above code snippet. Besides, if we want to include a CSS or JavaScript file in the current page, we need to register it using CClientScript:

A widget may also have its own view files. If so, create a directory named views under the directory containing the widget class file, and put all the view files there. In the widget class, in order to render a widget view, use \$this->render('ViewName'), which is similar to what we do in a controller.

6.3.3 Action

An action should extend from CAction or its child classes. The main method that needs to be implemented for an action is IAction::run.

6.3.4 Filter

A filter should extend from CFilter or its child classes. The main methods that need to be implemented for a filter are CFilter::preFilter and CFilter::postFilter. The former is invoked before the action is executed while the latter after.

```
class MyFilter extends CFilter
{
    protected function preFilter($filterChain)
```

```
{
    // logic being applied before the action is executed
    return true; // false if the action should not be executed
}

protected function postFilter($filterChain)
{
    // logic being applied after the action is executed
}
```

The parameter \$filterChain is of type CFilterChain which contains information about the action that is currently filtered.

6.3.5 Controller

A controller distributed as an extension should extend from CExtController, instead of CController. The main reason is because CController assumes the controller view files are located under application.views.ControllerID, while CExtController assumes the view files are located under the views directory which is a subdirectory of the directory containing the controller class file. Therefore, it is easier to redistribute the controller since its view files are staying together with the controller class file.

6.3.6 Validator

A validator should extend from CValidator and implement its CValidator::validateAttribute method.

6.3.7 Console Command

A console command should extend from CConsoleCommand and implement its CConsoleCommand::run method. Optionally, we can override CConsoleCommand::getHelp to provide some nice help information about the command.

90 6. Extending YII

```
class MyCommand extends CConsoleCommand
{
    public function run($args)
    {
        // $args gives an array of the command-line arguments for this command
    }
    public function getHelp()
    {
        return 'Usage: how to use this command';
    }
}
```

6.3.8 Module

The general guideline for developing a module is that it should be self-contained. Resource files (such as CSS, JavaScript, images) that are used by a module should be distributed together with the module. And the module should publish them so that they can be Web accessible.

6.3.9 Generic Component

Developing a generic component extension is like writing a class. Again, the component should also be self-contained so that it can be easily used by other developers.

6.4 Using 3rd-Party Libraries

Yii is carefully designed so that third-party libraries can be easily integrated to further extend Yii's functionalities. When using third-party libraries in a project, developers often encounter issues about class naming and file inclusion. Because all Yii classes are prefixed with letter C, it is less likely class naming issue would occur; and because Yii relies on SPL autoload to perform class file inclusion, it can play nicely with other libraries if they use the same autoloading feature or PHP include path to include class files.

Below we use an example to illustrate how to use the Zend_Search_Lucene component from the Zend framework in an Yii application.

First, we extract the Zend framework release file to a directory under protected/vendors, assuming protected is the application base directory. Verify that the file protected/vendors/Zend/Search/Lucene.php exists.

Second, at the beginning of a controller class file, insert the following lines:

```
Yii::import('application.vendors.*');
require_once('Zend/Search/Lucene.php');
```

The above code includes the class file Lucene.php. Because we are using a relative path, we need to change the PHP include path so that the file can be located correctly. This is done by calling Yii::import before require_once.

Once the above set up is ready, we can use the Lucene class in a controller action, like the following:

```
$lucene=new Zend_Search_Lucene($pathOfIndex);
$hits=$lucene->find(strtolower($keyword));
```

92 6. Extending YII

Special Topics

7.1 URL Management

Complete URL management for a Web application involves two aspects. First, when a user request comes in terms of a URL, the application needs to parse it into understandable parameters. Second, the application needs to provide a way of creating URLs so that the created URLs can be understood by the application. For an Yii application, these are accomplished with the help of CurlManager.

7.1.1 Creating URLs

Although URLs can be hardcoded in controller views, it is often more flexible to create them dynamically:

```
$url=$this->createUrl($route,$params);
```

where \$this refers to the controller instance; \$route specifies the route of the request; and \$params is a list of GET parameters to be appended to the URL.

By default, URLs created by createUrl is in the so-called get format. For example, given \$route='post/read' and \$params=array('id'=>100), we would obtain the following URL:

```
/index.php?r=post/read&id=100
```

where parameters appear in the query string as a list of Name=Value concatenated with the ampersand characters, and the r parameter specifies the request route. This URL format is not very user-friendly because it requires several non-word characters.

We could make the above URL look cleaner and more self-explanatory by using the socalled path format which eliminates the query string and puts the GET parameters into the path info part of URL: 94 7. Special Topics

/index.php/post/read/id/100

To change the URL format, we should configure the urlManager application component so that createUrl can automatically switch to the new format and the application can properly understand the new URLs:

Note that we do not need to specify the class of the urlManager component because it is pre-declared as CUrlManager in CWebApplication.

Tip: The URL generated by the createUrl method is a relative one. In order to get an absolute URL, we can prefix it with Yii::app()->hostInfo, or call createAbsoluteUrl.

7.1.2 User-friendly URLs

When path is used as the URL format, we can specify some URL rules to make our URLs even more user-friendly. For example, we can generate a URL as short as /post/100, instead of the lengthy /index.php/post/read/id/100. URL rules are used by CUrlManager for both URL creation and parsing purposes.

To specify URL rules, we need to configure the rules property of the urlManager application component:

```
array(
    .....
'components'=>array(
    .....
'urlManager'=>array(
    'urlFormat'=>'path',
    'rules'=>array(
        'pattern1'=>'route1',
        'pattern2'=>'route2',
```

The rules are specified as an array of pattern-route pairs, each corresponding to a single rule. The pattern of a rule must be a valid regular expression without delimiters and modifiers. It is used to match the path info part of URLs. And the route should refer to a valid controller route.

A rule can be associated with a few GET parameters. These GET parameters appear in the rule's pattern as special tokens of the following format:

```
<ParamName:ParamPattern>
```

where ParamName specifies the name of a GET parameter, and the optional ParamPattern specifies the regular expression that should be used to match the value of the GET parameter. When creating a URL, these parameter tokens will be replaced with the corresponding parameter values; when parsing a URL, the corresponding GET parameters will be populated with the parsed results.

Let's use some examples to explain how URL rules work. We assume that our rule set consists of three rules:

```
array(
    'posts'=>'post/list',
    'post/<id:\d+>'=>'post/read',
    'post/<year:\d{4}>/<title>'=>'post/read',
)
```

- Calling \$this->createUrl('post/list') generates /index.php/posts. The first rule is applied.
- Calling \$this->createUrl('post/read', array('id'=>100)) generates /index.php/post/ 100. The second rule is applied.
- Calling \$this->createUrl('post/read',array('year'=>2008,'title'=>'a sample post')) generates /index.php/post/2008/a%20sample%20post. The third rule is applied.
- Calling \$this->createUrl('post/read') generates /index.php/post/read. None of the rules is applied.

96 7. Special Topics

In summary, when using createUrl to generate a URL, the route and the GET parameters passed to the method are used to decide which URL rule to be applied. If every parameter associated with a rule can be found in the GET parameters passed to createUrl, and if the route of the rule also matches the route parameter, the rule will be used to generate the URL.

If the GET parameters passed to createUrl are more than those required by a rule, the additional parameters will appear in the query string. For example, if we call \$this->createUrl('post/read',array('id'=>100,'year'=>2008)), we would obtain /index.php/post/100?year=2008. In order to make these additional parameters appear in the path info part, we should append /* to the rule. Therefore, with the rule post/<id:\d+>/*, we can obtain the URL as /index.php/post/100/year/2008.

As we mentioned, the other purpose of URL rules is to parse the requesting URLs. Naturally, this is an inverse process of URL creation. For example, when a user requests for /index.php/post/100, the second rule in the above example will apply, which resolves in the route post/read and the GET parameter array('id'=>100) (accessible via \$_GET).

Note: Using URL rules will degrade application performance. This is because when parsing the request URL, CUrlManager will attempt to match it with each rule until one can be applied. Therefore, a high-traffic Web application should minimize its use of URL rules.

Hiding index.php

There is one more thing that we can do to further clean our URLs, i.e., hiding the entry script index.php in the URL. This requires us to configure the Web server as well as the urlManager application component.

We first need to configure the Web server so that a URL without the entry script can still be handled by the entry script. For Apache HTTP server, this can be done by turning on the URL rewriting engine and specifying some rewriting rules. Both can be in a . htaccess file that is placed under the directory containing the entry script. The following is an example:

```
Options +FollowSymLinks
IndexIgnore */*
RewriteEngine on

# if a directory or a file exists, use it directly
RewriteCond %{REQUEST_FILENAME} !-f
```

```
RewriteCond %{REQUEST_FILENAME} !-d

# otherwise forward it to index.php

RewriteRule . index.php
```

We then configure the showScriptName property of the urlManager component to be false.

Now if we call \$this->createUrl('post/read',array('id'=>100)), we would obtain the URL /post/100. More importantly, this URL can be properly recognized by our Web application.

Faking URL Suffix

We may also add some suffix to our URLs. For example, we can have /post/100.html instead of /post/100. This makes it look more like a URL to a static Web page. To do so, simply configure the urlManager component by setting its urlSuffix property to the suffix you like.

7.2 Authentication and Authorization

Authentication and authorization are required for a Web page that should be limited to certain users. Authentication is about verifying whether someone is who he claims he is. It usually involves a username and a password, but may include any other methods of demonstrating identity, such as a smart card, fingerprints, etc. Authorization is finding out if the person, once identified (authenticated), is permitted to manipulate specific resources. This is usually determined by finding out if that person is of a particular role that has access to the resources.

Yii has a built-in authentication/authorization (auth) framework which is easy to use and can be customized for special needs.

The central piece in the Yii auth framework is a pre-declared user application component which is an object implementing the IWebUser interface. The user component represents the persistent identity information for the current user. We can access it at any place using Yii::app()->user.

Using the user component, we can check if a user is logged in or not via CWebUser::isGuest; we can login and logout a user; we can check if the user can perform specific operations by calling CWebUser::checkAccess; and we can also obtain the unique identifier and other persistent identity information about the user.

7.2.1 Defining Identity Class

In order to authenticate a user, we define an identity class which contains the actual authentication logic. The identity class should implement the IUserIdentity interface. Different classes may be implemented for different authentication approaches (e.g. OpenID, LDAP). A good start is by extending CUserIdentity which is a base class for the authentication approach based on username and password.

The main work in defining an identity class is the implementation of the IUserIdentity::authenticate method. An identity class may also declare additional identity information that needs to be persistent during the user session.

In the following example, we validate the given username and password against the user table in a database using Active Record. We also define the title property to be persistent using CBaseUserIdentity::getState and CBaseUserIdentity::setState methods. As a result, during the whole user session, we can obtain the user title information via Yii::app()->user->getState('title').

Info: By default, CWebUser uses session as persistent storage for user identity information. If cookie-based login is enabled (by setting CWebUser::allowAutoLogin to be true), the user identity information may also be saved in cookie. Make sure you do not declare sensitive information (e.g. password) to be persistent.

7.2.2 Login and Logout

Using the identity class and the user component, we can implement login and logout actions easily.

```
// Login a user with the provided username and password.
$identity=new UserIdentity($username,$password);
if($identity=>authenticate())
    Yii::app()=>user=>login($identity);
else
    echo $identity=>errorMessage;
......
// Logout the current user
Yii::app()=>user=>logout();
```

By default, a user will be logged out after a certain period of inactivity, depending on the session configuration. To change this behavior, we can set the allowAutoLogin property of the user component to be true and pass a duration parameter to the CWebUser::login method. The user will then remain logged in for the specified duration, even if he closes his browser window. Note that this feature requires the user's browser to accept cookies.

```
// Keep the user logged in for 7 days.
// Make sure allowAutoLogin is set true for the user component.
Yii::app()->user->login($identity,3600*24*7);
```

7.2.3 Access Control Filter

Access control filter is a preliminary authorization scheme that checks if the current user can perform the requested controller action. The authorization is based on user's name, client IP address and request types. It is provided as a filter named as "accessControl".

Tip: Access control filter is sufficient for simple scenarios. For complex access control, you may use role-based access (RBAC) which is to be covered shortly.

To control the access to actions in a controller, we install the access control filter by overriding CController::filters (see Filter for more details about installing filters).

In the above, we specify that the access control filter should be applied to every action of PostController. The detailed authorization rules used by the filter are specified by overriding CController::accessRules in the controller class.

```
class PostController extends CController
    . . . . . .
    public function accessRules()
        return array(
            array('deny',
                 'actions'=>array('create', 'edit'),
                 'users'=>array('?'),
            ),
             array('allow',
                 'actions'=>array('delete'),
                 'roles'=>array('admin'),
            array('deny',
                 'actions'=>array('delete'),
                 'users'=>array('*'),
            ),
        );
    }
}
```

The above code specifies three rules, each represented as an array. The first element of the array is either 'allow' or 'deny' and the rest name-value pairs specify the pattern parameters of the rule. These rules read: the create and edit actions cannot be executed by anonymous users; the delete action can be executed by users with admin role; and the delete action cannot be executed by anyone.

The access rules are evaluated one by one in the order they are specified. The first rule that matches the current pattern (e.g. username, roles, client IP, address) determines the

authorization result. If this rule is an allow rule, the action can be executed; if it is a deny rule, the action cannot be executed; if none of the rules matches the context, the action can still be executed.

Tip: To ensure an action does not get executed under certain contexts, it is beneficial to always specify a matching-all **deny** rule at the end of rule set, like the following:

```
return array(
    // ... other rules...
    // the following rule denies 'delete' action for all contexts
    array('deny',
        'action'=>'delete',
    ),
);
```

The reason for this rule is because if none of the rules matches a context, an action will be executed.

An access rule can match the following context parameters:

- actions: specifies which actions this rule matches.
- users: specifies which users this rule matches. The current user's name is used for matching. Three special characters can be used here:
 - → *: any user, including both anonymous and authenticated users.
 - ?: anonymous users.
 - **@**: authenticated users.
- roles: specifies which roles that this rule matches. This makes use of the feature to be described in the next subsection. In particular, the rule is applied if CWebUser::checkAccess returns true for one of the roles. Note, you should mainly use roles in an allow rule because by definition, a role represents a permission to do something.
- ips: specifies which client IP addresses this rule matches.
- verbs: specifies which request types (e.g. GET, POST) this rule matches.

Handling Authorization Result

When authorization fails, i.e., the user is not allowed to perform the specified action, one of the following two scenarios may happen:

- If the user is not logged in and if the loginUrl property of the user component is configured to be the URL of the login page, the browser will be redirected to that page.
- Otherwise an HTTP exception will be displayed with error code 401.

When configuring the loginUrl property, one can provide a relative or absolute URL. One can also provide an array which will be used to generate a URL by calling CWebApplication::createUrl. The first array element should specify the route to the login controller action, and the rest name-value pairs are GET parameters. For example,

If the browser is redirected to the login page and the login is successful, we may want to redirect the browser back to the page that caused the authorization failure. How do we know the URL for that page? We can get this information from the returnUrl property of the user component. We can thus do the following to perform the redirection:

```
Yii::app()->request->redirect(Yii::app()->user->returnUrl);
```

7.2.4 Role-Based Access Control

Role-Based Access Control (RBAC) provides a simple yet powerful centralized access control. Please refer to the Wiki article for more details about comparing RBAC with other more traditional access control schemes.

Yii implements a hierarchical RBAC scheme via its authManager application component. In the following ,we first introduce the main concepts used in this scheme; we then describe how to define authorization data; at the end we show how to make use of the authorization data to perform access checking.

Overview

A fundamental concept in Yii's RBAC is authorization item. An authorization item is a permission to do something (e.g. creating new blog posts, managing users). According to its granularity and targeted audience, authorization items can be classified as operations, tasks and roles. A role consists of tasks, a task consists of operations, and an operation is a permission that is atomic. For example, we can have a system with administrator role which consists of post management task and user management task. The user management task may consist of create user, update user and delete user operations. For more flexibility, Yii also allows a role to consist of other roles or operations, a task to consist of other tasks, and an operation to consist of other operations.

An authorization item is uniquely identified by its name.

An authorization item may be associated with a business rule. A business rule is a piece of PHP code that will be executed when performing access checking with respect to the item. Only when the execution returns true, will the user be considered to have the permission represented by the item. For example, when defining an operation updatePost, we would like to add a business rule that checks if the user ID is the same as the post's author ID so that only the author himself can have the permission to update a post.

Using authorization items, we can build up an *authorization hierarchy*. An item A is a parent of another item B in the hierarchy if A consists of B (or say A inherits the permission(s) represented by B). An item can have multiple child items, and it can also have multiple parent items. Therefore, an authorization hierarchy is a partial-order graph rather than a tree. In this hierarchy, role items sit on top levels, operation items on bottom levels, while task items in between.

Once we have an authorization hierarchy, we can assign roles in this hierarchy to application users. A user, once assigned with a role, will have the permissions represented by the role. For example, if we assign the administrator role to a user, he will have the administrator permissions which include post management and user management (and the corresponding operations such as create user).

Now the fun part starts. In a controller action, we want to check if the current user can delete the specified post. Using the RBAC hierarchy and assignment, this can be done easily as follows:

```
if(Yii::app()->user->checkAccess('deletePost'))
{
    // delete the post
}
```

Configuring Authorization Manager

Before we set off to define an authorization hierarchy and perform access checking, we need to configure the authManager application component. Yii provides two types of authorization managers: CPhpAuthManager and CDbAuthManager. The former uses a PHP script file to store authorization data, while the latter stores authorization data in database. When we configure the authManager application component, we need to specify which component class to use and what are the initial property values for the component. For example,

```
return array(
    'components'=>array(
        'db'=>array(
          'class'=>'CDbConnection',
          'connectionString'=>'sqlite:path/to/file.db',
     ),
     'authManager'=>array(
          'class'=>'CDbAuthManager',
          'connectionID'=>'db',
     ),
    ),
   ),
);
```

We can then access the authManager application component using Yii::app()->authManager.

Defining Authorization Hierarchy

Defining authorization hierarchy involves three steps: defining authorization items, establishing relationships between authorization items, and assigning roles to application users. The authManager application component provides a whole set of APIs to accomplish these tasks.

To define an authorization item, call one of the following methods, depending on the type of the item:

- CAuthManager::createRole
- $\bullet \ \ CAuth Manager :: create Task$
- CAuthManager::createOperation

Once we have a set of authorization items, we can call the following methods to establish relationships between authorization items:

- CAuthManager::addItemChild
- CAuthManager::removeItemChild
- CAuthItem::addChild
- CAuthItem::removeChild

And finally, we call the following methods to assign role items to individual users:

- CAuthManager::assign
- CAuthManager::revoke

Below we show an example about building an authorization hierarchy with the provided APIs:

```
$auth=Yii::app()->authManager;
$auth->createOperation('createPost','create a post');
$auth->createOperation('readPost','read a post');
$auth->createOperation('updatePost', 'update a post');
$auth->createOperation('deletePost','delete a post');
$bizRule='return Yii::app()->user->id==$params["post"]->authID;';
$task=$auth->createTask('updateOwnPost','update a post by author himself',$bizRule);
$task->addChild('updatePost');
$role=$auth->createRole('reader');
$role->addChild('readPost');
$role=$auth->createRole('author');
$role->addChild('reader');
$role->addChild('createPost');
$role->addChild('updateOwnPost');
$role=$auth->createRole('editor');
$role->addChild('reader');
$role->addChild('updatePost');
$role=$auth->createRole('admin');
$role->addChild('editor');
$role->addChild('author');
$role->addChild('deletePost');
$auth->assign('reader', 'readerA');
```

```
$auth->assign('author', 'authorB');
$auth->assign('editor', 'editorC');
$auth->assign('admin', 'adminD');
```

Note that we associate a business rule with the updateOwnPost task. In the business rule we simply check if the current user ID is the same as the specified post's author ID. The post information in the \$params array is supplied by developers when performing access checking.

Info: While the above example looks long and tedious, it is mainly for demonstrative purpose. Developers usually need to develop some user interfaces so that end users can use to establish an authorization hierarchy more intuitively.

Access Checking

To perform access checking, we first need to know the name of the authorization item. For example, to check if the current user can create a post, we would check if he has the permission represented by the createPost operation. We then call CWebUser::checkAccess to perform the access checking:

```
if(Yii::app()->user->checkAccess('createPost'))
{
    // create post
}
```

If the authorization rule is associated with a business rule which requires additional parameters, we can pass them as well. For example, to check if a user can update a post, we would do

```
$params=array('post'=>$post);
if(Yii::app()->user->checkAccess('updateOwnPost',$params))
{
    // update post
}
```

7.3 Theme

Theming is a systematic way of customizing the outlook of pages in a Web application. By applying a new theme, the overall appearance of a Web application can be changed instantly and dramatically.

7.4 Logging 107

In Yii, each theme is represented as a directory consisting of view files, layout files, and relevant resource files such as images, CSS files, JavaScript files, etc. The name of a theme is its directory name. All themes reside under the same directory WebRoot/themes. At any time, only one theme can be active.

Tip: The default theme root directory WebRoot/themes can be configured to be a different one. Simply configure the basePath and the baseUrl properties of the themeManager application component to be the desired ones.

When we call render or renderPartial to display a view, the corresponding view file as well as the layout file will be looked for in the currently active theme. And if found, those files will be rendered. Otherwise, it falls back to the default location as specified by viewPath and layoutPath.

To activate a theme, set the theme property of the Web application to be the name of the desired theme. This can be done either in the application configuration or during runtime in controller actions.

Note: Theme name is case-sensitive. If you attempt to activate a theme that does not exist, Yii::app()->theme will return null.

Contents under a theme directory should be organized in the same way as those under the application base path. For example, all view files must be located under views, layout view files under views/layouts, and system view files under views/system. Because the views directory may contain security-sensitive data, it should be configured to prevent from being accessed by Web users.

Tip: Inside a theme view, we often need to link other theme resource files. For example, we may want to show an image file under the theme's images directory. Using the baseUrl property of the currently active theme, we can generate the URL for the image as follows,

Yii::app()->theme->baseUrl . '/images/FileName.gif'

7.4 Logging

Yii provides a flexible and extensible logging feature. Messages logged can be classified according to log levels and message categories. Using level and category filters, selected

messages can be further routed to different destinations, such as files, emails, browser windows, etc.

7.4.1 Message Logging

Messages can be logged by calling either Yii::log or Yii::trace. The difference between these two methods is that the latter logs a message only when the application is in debug mode.

```
Yii::log($message, $level, $category);
Yii::trace($message, $category);
```

When logging a message, we need to specify its category and level. Category is a string in the format of xxx.yyy.zzz which resembles to the path alias. For example, if a message is logged in CController, we may use the category system.web.CController. Message level should be one of the following values:

- trace: this is the level used by Yii::trace. It is for tracing the execution flow of the application during development.
- info: this is for logging general information.
- profile: this is for performance profile which is to be described shortly.
- warning: this is for warning messages.
- error: this is for fatal error messages.

7.4.2 Message Routing

Messages logged using Yii::log or Yii::trace are kept in memory. We usually need to display them in browser windows, or save them in some persistent storage such as files, emails. This is called *message routing*, i.e., sending messages to different destinations.

In Yii, message routing is managed by a CLogRouter application component. It manages a set of the so-called *log routes*. Each log route represents a single log destination. Messages sent along a log route can be filtered according to their levels and categories.

To use message routing, we need to install and preload a CLogRouter application component. We also need to configure its routes property with the log routes that we want. The following shows an example of the needed application configuration:

7.4 Logging 109

```
array(
    . . . . . .
    'preload'=>array('log'),
    'components'=>array(
         . . . . . .
        'log'=>array(
             'class'=>'CLogRouter',
             'routes'=>array(
                 array(
                      'class'=>'CFileLogRoute',
                     'levels'=>'trace, info',
                     'categories'=>'system.*',
                 ),
                 array(
                      'class'=>'CEmailLogRoute',
                     'levels'=>'error, warning',
                      'email'=>'admin@example.com',
                 ),
            ),
       ),
    ),
)
```

In the above example, we have two log routes. The first route is CFileLogRoute which saves messages in a file under the application runtime directory. Only messages whose level is trace or info and whose category starts with system. are saved. The second route is CEmailLogRoute which sends messages to the specified email addresses. Only messages whose level is error or warning are sent.

The following log routes are available in Yii:

- CDbLogRoute: saves messages in a database table.
- CEmailLogRoute: sends messages to specified email addresses.
- CFileLogRoute: saves messages in a file under the application runtime directory.
- CWebLogRoute: displays messages at the end of the current Web page.
- CProfileLogRoute: displays profiling messages at the end of the current Web page.

Info: Message routing occurs at the end of the current request cycle when the onEndRequest event is raised. To explicitly terminate the processing of the current request, call CApplication::end() instead of die() or exit(), because CApplication::end() will raise the onEndRequest event so that the messages can be properly logged.

Message Filtering

As we mentioned, messages can be filtered according to their levels and categories before they are sent long a log route. This is done by setting the levels and categories properties of the corresponding log route. Multiple levels or categories should be concatenated by commas.

Because message categories are in the format of xxx.yyy.zzz, we may treat them as a category hierarchy. In particular, we say xxx is the parent of xxx.yyy which is the parent of xxx.yyy.zzz. We can then use xxx.* to represent category xxx and all its child and grandchild categories.

7.4.3 Performance Profiling

Performance profiling is a special type of message logging. Performance profiling can be used to measure the time needed for the specified code blocks and find out what the performance bottleneck is.

To use performance profiling, we need to identify which code blocks need to be profiled. We mark the beginning and the end of each code block by inserting the following methods:

```
Yii::beginProfile('blockID');
...code block being profiled...
Yii::endProfile('blockID');
```

where blockID is an ID that uniquely identifies the code block.

Note, code blocks need to be nested properly. That is, a code block cannot intersect with another. It must be either at a parallel level or be completely enclosed by the other code block.

To show profiling result, we need to install a CLogRouter application component with a CProfileLogRoute log route. This is the same as we do with normal message routing. The CProfileLogRoute route will display the performance results at the end of the current page.

7.5 Error Handling

Yii provides a complete error handling framework based on the PHP 5 exception mechanism. When the application is created to handle an incoming user request, it registers its handleError method to handle PHP warnings and notices; and it registers its handleException method to handle uncaught PHP exceptions. Consequently, if a PHP warning/notice

or an uncaught exception occurs during the application execution, one of the error handlers will take over the control and start the necessary error handling procedure.

Tip: The registration of error handlers is done in the application's constructor by calling PHP functions set_exception_handler and set_error_handler. If you do not want Yii to handle the errors and exceptions, you may define constant YII_ENABLE_ERROR_HANDLER and YII_ENABLE_EXCEPTION_HANDLER to be false in the entry script.

By default, errorHandler (or exception) will raise an onError event (or onException event). If the error (or exception) is not handled by any event handler, it will call for help from the errorHandler application component.

7.5.1 Raising Exceptions

Raising exceptions in Yii is not different from raising a normal PHP exception. One uses the following syntax to raise an exception when needed:

```
throw new ExceptionClass('ExceptionMessage');
```

Yii defines two exception classes: CException and CHttpException. The former is a generic exception class, while the latter represents an exception that should be displayed to end users. The latter also carries a statusCode property representing an HTTP status code. The class of an exception determines how it should be displayed, as we will explain next.

Tip: Raising a CHttpException exception is a simple way of reporting errors caused by user misoperation. For example, if the user provides an invalid post ID in the URL, we can simply do the following to show a 404 error (page not found):

```
// if post ID is invalid
throw new CHttpException(404,'The specified post cannot be found.');
```

7.5.2 Displaying Errors

When an error is forwarded to the CErrorHandler application component, it chooses an appropriate view to display the error. If the error is meant to be displayed to end users, such as a CHttpException, it will use a view named errorXXX, where XXX stands for the HTTP status code (e.g. 400, 404, 500). If the error is an internal one and should only be displayed to developers, it will use a view named exception. In the latter case, complete call stack as well as the error line information will be displayed.

Info: When the application runs in production mode, all errors including those internal ones will be displayed using view errorXXX. This is because the call stack of an error may contain sensitive information. In this case, developers should rely on the error logs to determine what is the real cause of an error.

CErrorHandler searches for the view file corresponding to a view in the following order:

- 1. WebRoot/themes/ThemeName/views/system: this is the system view directory under the currently active theme.
- 2. WebRoot/protected/views/system: this is the default system view directory for an application.
- 3. yii/framework/views: this is the standard system view directory provided by the Yii framework.

Therefore, if we want to customize the error display, we can simply create error view files under the system view directory of our application or theme. Each view file is a normal PHP script consisting of mainly HTML code. For more details, please refer to the default view files under the framework's view directory.

7.5.3 Message Logging

A message of level error will always be logged when an error occurs. If the error is caused by a PHP warning or notice, the message will be logged with category php; if the error is caused by an uncaught exception, the category would be exception. ExceptionClassName (for CHttpException its statusCode will also be appended to the category). One can thus exploit the logging feature to monitor errors happened during application execution.

7.6 Web Service

Web service is a software system designed to support interoperable machine-to-machine interaction over a network. In the context of Web applications, it usually refers to a set of APIs that can be accessed over the Internet and executed on a remote system hosting the requested service. For example, a Flex-based client may invoke a function implemented on the server side running a PHP-based Web application. Web service relies on SOAP as its foundation layer of the communication protocol stack.

Yii provides CWebService and CWebServiceAction to simplify the work of implementing Web service in a Web application. The APIs are grouped into classes, called *service*

7.6 Web Service 113

providers. Yii will generate for each class a WSDL specification which describes what APIs are available and how they should be invoked by client. When an API is invoked by a client, Yii will instantiate the corresponding service provider and call the requested API to fulfill the request.

Note: CWebService relies on the PHP SOAP extension. Make sure you have enabled it before trying the examples displayed in this section.

7.6.1 Defining Service Provider

As we mentioned above, a service provider is a class defining the methods that can be remotely invoked. Yii relies on doc comment and class reflection to identify which methods can be remotely invoked and what are their parameters and return value.

Let's start with a simple stock quoting service. This service allows a client to request for the quote of the specified stock. We define the service provider as follows. Note that we define the provider class StockController by extending CController. This is not required. We will explain why we do so shortly.

In the above, we declare the method getPrice to be a Web service API by marking it with the tag @soap in its doc comment. We rely on doc comment to specify the data type of the input parameters and return value. Additional APIs can be declared in the similar way.

7.6.2 Declaring Web Service Action

Having defined the service provider, we need to make it available to clients. In particular, we want to create a controller action to expose the service. This can be done easily by

declaring a CWebServiceAction action in a controller class. For our example, we will just put it in StockController.

```
class StockController extends CController
{
    public function actions()
    {
        return array(
            'quote'=>array(
                'class'=>'CWebServiceAction',
                ),
        );
    }

    /**
    * @param string the symbol of the stock
    * @return float the stock price
    * @soap
    */
    public function getPrice($symbol)
    {
        //...return stock price for $symbol
    }
}
```

That is all we need to create a Web service! If we try to access the action by URL http://hostname/path/to/index.php?r=stock/quote, we will see a lot of XML content which is actually the WSDL for the Web service we defined.

Tip: By default, CWebServiceAction assumes the current controller is the service provider. That is why we define the getPrice method inside the StockController class.

7.6.3 Consuming Web Service

To complete the example, let's create a client to consume the Web service we just created. The example client is written in PHP, but it could be in other languages, such as Java, C#, Flex, etc.

```
$client=new SoapClient('http://hostname/path/to/index.php?r=stock/quote');
echo $client->getPrice('GOOGLE');
```

Run the above script in either Web or console mode, and we shall see 350 which is the price for GOOGLE.

7.6 Web Service 115

7.6.4 Data Types

When declaring class methods and properties to be remotely accessible, we need to specify the data types of the input and output parameters. The following primitive data types can be used:

- str/string: maps to xsd:string;
- int/integer: maps to xsd:int;
- float/double: maps to xsd:float;
- bool/boolean: maps to xsd:boolean;
- date: maps to xsd:date;
- time: maps to xsd:time;
- datetime: maps to xsd:dateTime;
- array: maps to xsd:string;
- object: maps to xsd:struct;
- mixed: maps to xsd:anyType.

If a type is not any of the above primitive types, it is considered as a composite type consisting of properties. A composite type is represented in terms of a class, and its properties are the class' public member variables marked with @soap in their doc comments.

We can also use array type by appending [] to the end of a primitive or composite type. This would specify an array of the specified type.

Below is an example defining the getPosts Web API which returns an array of Post objects.

```
class PostController extends CController
{
    /**
    * @return Post[] a list of posts
    * @soap
    */
    public function getPosts()
    {
        return Post::model()->findAll();
    }
}
```

```
class Post extends CActiveRecord
{
    /**
    * @var integer post ID
    * @soap
    */
    public $id;
    /**
    * @var string post title
    * @soap
    */
    public $title;
}
```

7.6.5 Class Mapping

In order to receive parameters of composite type from client, an application needs to declare the mapping from WSDL types to the corresponding PHP classes. This is done by configuring the classMap property of CWebServiceAction.

7.6.6 Intercepting Remote Method Invocation

By implementing the IWebServiceProvider interface, a sevice provider can intercept remote method invocations. In IWebServiceProvider::beforeWebMethod, the provider may retrieve the current CWebService instance and obtain the the name of the method currently being requested via CWebService::methodName. It can return false if the remote method should not be invoked for some reason (e.g. unauthorized access).

7.7 Internationalization

Internationalization (I18N) refers to the process of designing a software application so that it can be adapted to various languages and regions without engineering changes. For Web applications, this is of particular importance because the potential users may be from worldwide.

Yii provides support for I18N in several aspects.

- It provides the locale data for each possible language and variant.
- It provides message and file translation service.
- It provides locale-dependent date and time formatting.
- It provides locale-dependent number formatting.

In the following subsections, we will elaborate each of the above aspects.

7.7.1 Locale and Language

Locale is a set of parameters that defines the user's language, country and any special variant preferences that the user wants to see in their user interface. It is usually identified by an ID consisting of a language ID and a region ID. For example, the ID en_US stands for the locale of English and United States. For consistency, all locale IDs in Yii are canonicalized to the format of LanguageID or LanguageID_RegionID in lower case (e.g. en, en_us).

Locale data is represented as a CLocale instance. It provides locale-dependent information, including currency symbols, number symbols, currency formats, number formats, date and time formats, and date-related names. Since the language information is already implied in the locale ID, it is not provided by CLocale. For the same reason, we often interchangeably using the term locale and language.

Given a locale ID, one can get the corresponding CLocale instance by CLocale::getInstance(\$localeID) or CApplication::getLocale(\$localeID).

Info: Yii comes with locale data for nearly every language and region. The data is obtained from Common Locale Data Data Repository (CLDR). For each locale, only a subset of the CLDR data is provided as the original data contains much rarely used information.

For an Yii application, we differentiate its target language from source language. The target language is the language (locale) of the users that the application is targeted at, while the source language refers to the language (locale) that the application source files are written in. Internationalization occurs only when the two languages are different.

One can configure target language in the application configuration, or change it dynamically before any internationalization occurs.

Tip: Sometimes, we may want to set the target language as the language preferred by a user (specified in user's browser preference). To do so, we can retrieve the user preferred language ID using CHttpRequest::preferredLanguage.

7.7.2 Translation

The most needed I18N feature is perhaps translation, including message translation and view translation. The former translates a text message to the desired language, while the latter translates a whole file to the desired language.

A translation request consists of the object to be translated, the source language that the object is in, and the target language that the object needs to be translated to. In Yii, the source language is default to the application source language while the target language is default to the application language. If the source and target languages are the same, translation will not occur.

Message Translation

Message translation is done by calling Yii::t(). The method translates the given message from source language to target language.

When translating a message, its category has to be specified since a message may be translated differently under different categories (contexts). The category yii is reserved for messages used by the Yii framework core code.

Messages can contain parameter placeholders which will be replaced with the actual parameter values when calling Yii::t(). For example, the following message translation request would replace the {alias} placeholder in the original message with the actual alias value.

```
Yii::t('yii', 'Path alias "{alias}" is redefined.',
    array('{alias}'=>$alias))
```

Note: Messages to be translated must be constant strings. They should not contain variables that would change message content (e.g. "Invalid {\$message} content."). Use parameter placeholders if a message needs to vary according to some parameters.

Translated messages are stored in a repository called *message source*. A message source is represented as an instance of CMessageSource or its child class. When Yii::t() is invoked, it will look for the message in the message source and return its translated version if it is found.

Yii comes with the following types of message sources. You may also extend CMessage-Source to create your own message source type.

- CPhpMessageSource: the message translations are stored as key-value pairs in a PHP array. The original message is the key and the translated message is the value. Each array represents the translations for a particular category of messages and is stored in a separate PHP script file whose name is the category name. The PHP translation files for the same language are stored under the same directory named as the locale ID. And all these directories are located under the directory specified by basePath.
- CGettextMessageSource: the message translations are stored as GNU Gettext files.
- CDbMessageSource: the message translations are stored in database tables. For more details, see the API documentation for CDbMessageSource.

A message source is loaded as an application component. Yii pre-declares an application component named messages to store messages that are used in user application. By default, the type of this message source is CPhpMessageSource and the base path for storing the PHP translation files is protected/messages.

In summary, in order to use message translation, the following steps are needed:

- 1. Call Yii::t() at appropriate places;
- 2. Create PHP translation files as protected/messages/LocaleID/CategoryName.php. Each file simply returns an array of message translations. Note, this assumes you are using the default CPhpMessageSource to store the translated messages.
- 3. Configure CApplication::sourceLanguage and CApplication::language.

Tip: The yiic tool in Yii can be used to manage message translations when CPh-pMessageSource is used as the message source. Its message command can automatically extract messages to be translated from selected source files and merge them with existing translations if necessary.

Since version 1.0.2, Yii has added the support for choice format. Choice format refers to choosing a translated according to a given number value. For example, in English the word 'book' may either take a singular form or a plural form depending on the number of books, while in other languages, the word may not have different form (such as Chinese) or may have more complex plural form rules (such as Russian). Choice format solves this problem in a simple yet effective way.

To use choice format, a translated message must consist of a sequence of expression-message pairs separated by I, as shown below:

```
'expr1#message1|expr2#message2|expr3#message3'
```

where exprN refers to a valid PHP expression which evaluates to a boolean value indicating whether the corresponding message should be returned. Only the message corresponding to the first expression that evaluates to true will be returned. An expression can contain a special variable named n (note, it is not \$n) which will take the number value passed as the first message parameter. For example, assuming a translated message is:

```
'n==1#one book|n>1#many books'
```

and we are passing a number value 2 in the message parameter array when calling Yii::t(), we would obtain many books as the final translated message.

As a shortcut notation, if an expression is a number, it will be treated as n==Number. Therefore, the above translated message can be also be written as:

```
'1#one book|n>1#many books'
```

File Translation

File translation is accomplished by calling CApplication::findLocalizedFile(). Given the path of a file to be translated, the method will look for a file with the same name under

the LocaleID subdirectory. If found, the file path will be returned; otherwise, the original file path will be returned.

File translation is mainly used when rendering a view. When calling one of the render methods in a controller or widget, the view files will be translated automatically. For example, if the target language is zh_cn while the source language is en_us, rendering a view named edit would resulting in searching for the view file protected/views/ControllerID/zh_cn/edit.php. If the file is found, this translated version will be used for rendering; otherwise, the file protected/views/ControllerID/edit.php will be rendered instead.

File translation may also be used for other purposes, for example, displaying a translated image or loading a locale-dependent data file.

7.7.3 Date and Time Formatting

Date and time are often in different formats in different countries or regions. The task of date and time formatting is thus to generate a date or time string that fits for the specified locale. Yii provides CDateFormatter for this purpose.

Each CDateFormatter instance is associated with a target locale. To get the formatter associated with the target locale of the whole application, we can simply access the dateFormatter property of the application.

The CDateFormatter class mainly provides two methods to format a UNIX timestamp.

- format: this method formats the given UNIX timestamp into a string according to a customized pattern (e.g. \$dateFormatter->format('yyyy-MM-dd', \$timestamp)).
- formatDateTime: this method formats the given UNIX timestamp into a string according to a pattern predefined in the target locale data (e.g. short format of date, long format of time).

7.7.4 Number Formatting

Like data and time, numbers may also be formatted differently in different countries or regions. Number formatting includes decimal formatting, currency formatting and percentage formatting. Yii provides CNumberFormatter for these tasks.

To get the number formatter associated with the target locale of the whole application, we can access the numberFormatter property of the application.

The following methods are provided by CNumberFormatter to format an integer or double value.

• format: this method formats the given number into a string according to a customized pattern (e.g. \$numberFormatter->format('#,##0.00',\$number)).

- formatDecimal: this method formats the given number using the decimal pattern predefined in the target locale data.
- formatCurrency: this method formats the given number and currency code using the currency pattern predefined in the target locale data.
- formatPercentage: this method formats the given number using the percentage pattern predefined in the target locale data.

7.8 Using Alternative Template Syntax

Yii allows developers to use their own favorite template syntax (e.g. Prado, Smarty) to write controller or widget views. This is achieved by writing and installing a viewRenderer application component. The view renderer intercepts the invocations of CBaseController::renderFile, compiles the view file with customized template syntax, and renders the compiling results.

Info: It is recommended to use customized template syntax only when writing views that are less likely to be reused. Otherwise, people who are reusing the views would be forced to use the same customized template syntax in their applications.

In the following, we introduce how to use CPradoViewRenderer, a view renderer that allows developers to use the template syntax similar to that in Prado framework. For people who want to develop their own view renderers, CPradoViewRenderer is a good reference.

7.8.1 Using CPradoViewRenderer

To use CPradoViewRenderer, we just need to configure the application as follows:

By default, CPradoViewRenderer will compile source view files and save the resulting PHP files under the runtime directory. Only when the source view files are changed, will the PHP files be re-generated. Therefore, using CPradoViewRenderer incurs very little performance degradation.

Tip: While CPradoViewRenderer mainly introduces some new template tags to make writing views easier and faster, you can still write PHP code as usual in the source views.

In the following, we introduce the template tags that are supported by CPradoViewRenderer.

Short PHP Tags

Short PHP tags are shortcuts to writing PHP expressions and statements in a view. The expression tag <%= expression %> is translated into <?php echo expression ?>; while the statement tag <% statement %> to <?php statement ?>. For example,

```
<%= CHtml::textField($name,'value'); %>
<% foreach($models as $model): %>

is translated into

<?php echo CHtml::textField($name,'value'); ?>
<?php foreach($models as $model): ?>
```

Component Tags

Component tags are used to insert a widget in a view. It uses the following syntax:

```
<com:WidgetClass property1=value1 property2=value2 ...>
    // body content for the widget
</com:WidgetClass>

// a widget without body content
<com:WidgetClass property1=value1 property2=value2 .../>
```

where WidgetClass specifies the widget class name or class path alias, and property initial values can be either quoted strings or PHP expressions enclosed within a pair of curly brackets. For example,

```
<com:CCaptcha captchaAction="captcha" showRefreshButton={false} />
would be translated as

<com:CCaptcha captchaAction="captcha" showRefreshButton={false} />
captchaAction; array(
    'captchaAction; array(
    'captchaAction; array(
    'showRefreshButton; array(
    'showRefreshButton; array(
    'showRefreshButton; array(
    'showRefreshButton; array(
    'showRefreshButton; array(
    'captchaAction; array(
    'showRefreshButton; array(
    'captchaAction; array(
    'captchaAction; array(
    'captchaAction; array(
    'showRefreshButton; array(
    'captchaAction; array(
    'captchaAction; array(
    'showRefreshButton; array(
    'showRefreshButton; array(
    'captchaAction; array(
    'captchaAction; array(
    'captchaAction; array(
    'captchaAction; array(
    'captchaAction; array(
    'showRefreshButton; array(
    'captchaAction; array(
    'captchaActi
```

Note: The value for showRefreshButton is specified as {false} instead of "false" because the latter means a string instead of a boolean.

Cache Tags

Cache tags are shortcuts to using fragment caching. Its syntax is as follows,

```
<cache:fragmentID property1=value1 property2=value2 ...>
    // content being cached
</cache:fragmentID >
```

where fragmentID should be an identifier that uniquely identifies the content being cached, and the property-value pairs are used to configure the fragment cache. For example,

```
<cache:profile duration={3600}>
    // user profile information here
</cache:profile >

would be translated as

<?php if($this->cache('profile', array('duration'=>3600))): ?>
    // user profile information here
<?php $this->endCache(); endif; ?>
```

Clip Tags

Like cache tags, clip tags are shortcuts to calling CBaseController::beginClip and CBaseController::endClip in a view. The syntax is as follows,

```
<clip:clipID>
    // content for this clip
</clip:clipID >
```

where clipID is an identifier that uniquely identifies the clip content. The clip tags will be translated as

```
<?php $this->beginClip('clipID'); ?>
    // content for this clip
<?php $this->endClip(); ?>
```

Comment Tags

Comment tags are used to write view comments that should only be visible to developers. Comment tags will be stripped off when the view is displayed to end users. The syntax for comment tags is as follows,

```
<!---
view comments that will be stripped off
--->
```

7.9 Console Applications

Console applications are mainly used by a Web application to perform offline work, such as code generation, search index compiling, email sending, etc. Yii provides a framework for writing console applications in an object-oriented and systematic way.

Yii represents each console task in terms of a command, and a console application instance is used to dispatch a command line request to an appropriate command. The application instance is created in an entry script. To execute a console task, we simply run the corresponding command on the command line as follows,

```
php entryScript.php CommandName Param0 Param1 ...
```

where CommandName refers to the command name which is case-insensitive, and ParamO, Param1 and so on are parameters to be passed to the command instance.

The entry script for a console application is usually written like the following, similar to that in a Web application,

```
defined('YII_DEBUG') or define('YII_DEBUG',true);
// include Yii bootstrap file
require_once('path/to/yii/framework/yii.php');
// create application instance and run
$configFile='path/to/config/file.php';
Yii::createConsoleApplication($configFile)->run();
```

We then create command classes which should extend from CConsoleCommand. Each command class should be named as its command name appended with Command. For example, to define an email command, we should write an EmailCommand class. All command class files should be placed under the commands subdirectory of the application base directory.

Tip: By configuring CConsoleApplication::commandMap, one can also have command classes in different naming conventions and located in different directories.

Writing a command class mainly involves implementing the CConsoleCommand::run method. Command line parameters are passed as an array to this method. Below is an example:

```
class EmailCommand extends CConsoleCommand
{
    public function run($args)
    {
        $receiver=$args[0];
        // send email to $receiver
    }
}
```

At any time in a command, we can access the console application instance via Yii::app(). Like a Web application instance, console application can also be configured. For example, we can configure a db application component to access the database. The configuration is usually specified as a PHP file and passed to the constructor of the console application class (or createConsoleApplication in the entry script).

7.9.1 Using the yiic Tool

We have used the yiic tool to create our first application. The yiic tool is in fact implemented as a console application whose entry script file is framework/yiic.php. Using yiic, we can accomplish tasks such as creating a Web application skeleton, generating a controller class or model class, generating code needed by CRUD operations, extracting messages to be translated, etc.

7.10 Security 127

We can enhance yiic by adding our own customized commands. To do so, we should start with a skeleton application created using yiic webapp command, as described in Creating First Yii Application. The yiic webapp command will generate two files under the protected directory: yiic and yiic.bat. They are the *local* version of the yiic tool created specifically for the Web application.

We can then create our own commands under the protected/commands directory. Run the local yiic tool, we will see that our own commands appearing together with the standard ones. We can also create our own commands to be used when yiic shell is used. To do so, just drop our command class files under the protected/commands/shell directory.

7.10 Security

7.10.1 Cross-site Scripting Prevention

Cross-site scripting (also known as XSS) occurs when a web application gathers malicious data from a user. Often attackers will inject JavaScript, VBScript, ActiveX, HTML, or Flash into a vulnerable application to fool other application users and gather data from them. For example, a poorly design forum system may display user input in forum posts without any checking. An attacker can then inject a piece of malicious JavaScript code into a post so that when other users read this post, the JavaScript runs unexpectedly on their computers.

One of the most important measures to prevent XSS attacks is to check user input before displaying them. One can do HTML-encoding with the user input to achieve this goal. However, in some situations, HTML-encoding may not be preferable because it disables all HTML tags.

Yii incorporates the work of HTMLPurifier and provides developers with a useful component called CHtmlPurifier that encapsulates HTMLPurifier. This component is capable of removing all malicious code with a thoroughly audited, secure yet permissive whitelist and making sure the filtered content is standard-compliant.

The CHtmlPurifier component can be used as either a widget or a filter. When used as a widget, CHtmlPurifier will purify contents displayed in its body in a view. For example,

```
<?php $this->beginWidget('CHtmlPurifier'); ?>
...display user-entered content here...
<?php $this->endWidget(); ?>
```

7.10.2 Cross-site Request Forgery Prevention

Cross-Site Request Forgery (CSRF) attacks occur when a malicious web site causes a users web browser to perform an unwanted action on a trusted site. For example, a malicious web site has a page that contains an image tag whose src points to a banking site: http://bank.example/withdraw?transfer=10000&to=someone. If a user who has a login cookie for the banking site happens to visit this malicous page, the action of transferring 10000 dollars to someone will be executed. Contrary to cross-site, which exploits the trust a user has for a particular site, CSRF exploits the trust that a site has for a particular user.

To prevent CSRF attacks, it is important to abide to the rule that GET requests should only be allowed to retrieve data rather than modify any data on the server. And for POST requests, they should include some random value which can be recognized by the server to ensure the form is submitted from and the result is sent back to the same origin.

Yii implements a CSRF prevention scheme to help defeat POST-based attacks. It is based on storing a random value in a cookie and comparing this value with the value submitted via the POST request.

By default, the CSRF prevention is disabled. To enable it, configure the CHttpRequest application component in the application configuration as follows,

And to display a form, call CHtml::form instead of writing the HTML form tag directly. The CHtml::form method will embed the necessary random value in a hidden field so that it can be submitted for CSRF validation.

7.10.3 Cookie Attack Prevention

Protecting cookies from being attacked is of extreme important, as session IDs are commonly stored in cookies. If one gets hold of a session ID, he essentially owns all relevant session information.

There are several countermeasures to prevent cookies from being attacked.

• An application can use SSL to create a secure communication channel and only pass

the authentication cookie over an HTTPS connection. Attackers are thus unable to decipher the contents in the transferred cookies.

- Expire sessions appropriately, including all cookies and session tokens, to reduce the likelihood of being attacked.
- Prevent cross-site scripting which causes arbitrary code to run in a user's browser and expose his cookies.
- Validate cookie data and detect if they are altered.

Yii implements a cookie validation scheme that prevents cookies from being modified. In particular, it does HMAC check for the cookie values if cookie validation is enable.

Cookie validation is disabled by default. To enable it, configure the CHttpRequest application component in the application configuration as follows,

To make use of the cookie validation scheme provided by Yii, we also need to access cookies through the cookies collection, instead of directly trhough \$_COOKIES:

```
// retrieve the cookie with the specified name
$cookie=Yii::app()->request->cookies[$name];
$value=$cookie->value;
.....
// send a cookie
$cookie=new CHttpCookie($name,$value);
Yii::app()->request->cookies[$name]=$cookie;
```

7.11 Performance Tuning

Performance of Web applications is affected by many factors. Database access, file system operations, network bandwidth are all potential affecting factors. Yii has tried in every aspect to reduce the performance impact caused by the framework. But still, there are many places in the user application that can be improved to boost performance.

7.11.1 Enabling APC Extension

Enabling the PHP APC extension is perhaps the easiest way to improve the overall performance of an application. The extension caches and optimizes PHP intermediate code and avoids the time spent in parsing PHP scripts for every incoming request.

7.11.2 Disabling Debug Mode

Disabling debug mode is another easy way to improve performance. An Yii application runs in debug mode if the constant YII_DEBUG is defined as true. Debug mode is useful during development stage, but it would impact performance because some components cause extra burden in debug mode. For example, the message logger may record additional debug information for every message being logged.

7.11.3 Using yiilite.php

When the PHP APC extension is enabled, we can replace yii.php with a different Yii bootstrap file named yiilite.php to further boost the performance of an Yii-powered application.

The file yiilite.php comes with every Yii release. It is the result of merging some commonly used Yii class files. Both comments and trace statements are stripped from the merged file. Therefore, using yiilite.php would reduce the number of files being included and avoid execution of trace statements.

Note, using yiilite.php without APC may actually reduce performance, because yiilite. php contains some classes that are not necessarily used in every request and would take extra parsing time. It is observed that using yiilite.php is slower with some server configurations, even when APC is turned on. The best way to judge whether to use yiilite.php or not is to run a benchmark using the included hello world demo.

7.11.4 Using Caching Techniques

As described in the Caching section, Yii provides several caching solutions that may improve the performance of a Web application significantly. If the generation of some data takes long time, we can use the data caching approach to reduce the data generation frequency; If a portion of page remains relatively static, we can use the fragment caching approach to reduce its rendering frequency; If a whole page remains relative static, we can use the page caching approach to save the rendering cost for the whole page.

If the application is using Active Record, we should turn on the schema caching to save the time of parsing database schema. This can be done by configuring the CDbConnection::schemaCachingDuration property to be a value greater than 0.

Besides these application-level caching techniques, we can also use server-level caching solutions to boost the application performance. As a matter of fact, the APC caching we described earlier belongs to this category. There are other server techniques, such as Zend Optimizer, eAccelerator, Squid, to name a few.

7.11.5 Database Optimization

Fetching data from database is often the main performance bottleneck in a Web application. Although using caching may alleviate the performance hit, it does not fully solve the problem. When the database contains enormous data and the cached data is invalid, fetching the latest data could be prohibitively expensive without proper database and query design.

Design index wisely in a database. Indexing can make SELECT queries much faster, but it may slow down INSERT, UPDATE or DELETE queries.

For complex queries, it is recommended to create a database view for it instead of issuing the queries inside the PHP code and asking DBMS to parse them repetitively.

Do not overuse Active Record. Although Active Record is good at modelling data in an OOP fashion, it actually degrades performance due to the fact that it needs to create one or several objects to represent each row of query result. For data intensive applications, using DAO or database APIs at lower level could be a better choice.

Last but not least, use LIMIT in your SELECT queries. This avoids fetching overwhelming data from database and exhausting the memory allocated to PHP.
